Treatment Principles

Prompt institution of appropriate antimicrobial therapy is essential when treating meningitis. Delay in antibiotic administration is associated with increased morbidity and mortality.[9] When choosing antimicrobial therapy, a number of factors must be considered. First, the antibiotics selected must penetrate adequately into the CSF. In addition, the regimen chosen must have potent activity against known or suspected pathogens and exert a bactericidal effect.[28]

ANTIMICROBIAL PENETRATION INTO THE CEREBROSPINAL FLUID

The ability of antimicrobials to penetrate the CSF is affected by lipid solubility, degree of ionization, molecular weight, protein binding, and susceptibility to active transport systems operative within the choroid plexus. In general, the penetration of most antibiotics into the CSF is increased when the meninges are inflamed. Antimicrobial penetration into the CSF is most commonly reported as a ratio of CSF to serum antimicrobial levels. **Table 65-4** summarizes the CSF penetration characteristics of various antimicrobials during acute bacterial meningitis.[28],[30] Metronidazole, sulfamethoxazole, and trimethoprim are small, highly lipophilic compounds and penetrate into the CSF well, achieving adequate concentrations even when meningeal inflammation is absent. Rifampin is lipophilic but is a larger compound with a high degree of protein binding. Thus, it achieves satisfactory CSF penetration and may be combined with vancomycin to treat coagulase-negative staphylococcal infections in the CNS. Because β-lactams usually are ionized at physiologic pH, they are more polar and do not penetrate the CSF as well. β-Lactams penetrate poorly when the meninges are intact, but when the meninges are inflamed, most penicillins and the third- and fourth-generation cephalosporins achieve CSF concentrations sufficient to treat meningitis (~10%–30% of simultaneously obtained serum concentrations). First- and second-generation cephalosporins are not recommended in the treatment of meningitis owing to inadequate penetration and/or inferior efficacy.[31],[32] Ceftriaxone achieves sustained, reliable bactericidal activity within the CSF despite its high protein binding and has been used successfully to treat meningitis in both children and adults. An additional factor working against maintenance of therapeutic concentrations of β-lactams in the CSF is the active transport system of the choroid plexus, which pumps these organic acids out of the CSF. Meropenem achieves CSF levels 10% to 40% of serum levels.[28],[30] Regarding β-lactamase inhibitors, there is sparse clinical data exploring their use in the treatment of CNS infections, and limited pharmacokinetic data with tazobactam and clavulanic acid raise concerns for inadequate CSF concentrations. High-dose sulbactam has been used with success in some patients with *Acinetobacter baumannii* meningitis.[30] However,

this is a unique scenario because sulbactam alone displays activity against *Acinetobacter*, and as such maintaining a ratio of β-lactam:β-lactamase inhibitor is not necessary. At the present time, data are too limited to draw conclusions on the utility of the newer agents such as ceftaroline or cefiderocol in the treatment of CNS infections.

Table 65-4
Cerebrospinal Fluid Penetration Characteristics of Various Antimicrobials

Very Good[a]
Commonly recommended: metronidazole (brain abscess), TMP-SMX (second line to ampicillin for empiric coverage of *Listeria*) Uncommonly utilized; reserve use for specific scenarios[b]: linezolid, rifampin, fluoroquinolones (ciprofloxacin, moxifloxacin, levofloxacin)
Good[c]
Penicillins: penicillin G, ampicillin, piperacillin, nafcillin
Other β-*lactams:* aztreonam, clavulanate, imipenem, meropenem, sulbactam, tazobactam
Third- and fourth-generation cephalosporins[d]: cefotaxime, ceftazidime, ceftriaxone, cefepime
Other agents: vancomycin, doxycycline
Fair to Poor[e]
Aminoglycosides: amikacin, gentamicin, tobramycin *Polymyxins: colistin, Polymyxin B*
First-generation cephalosporins: Cefazolin *Other agents:* macrolides (azithromycin, clarithromycin, erythromycin), clindamycin, daptomycin

TMP-SMX, trimethoprim–sulfamethoxazole.

[a]Generally achieve levels ≥20% of serum concentrations; generally penetrate cerebrospinal fluid (CSF) well regardless of meningeal inflammation.

[b]See text for details.

[c]Generally achieve levels 10% to 20% of serum concentrations; adequate CSF penetration achieved when the meninges are inflamed.

[d]Cefuroxime has similar central nervous system (CNS) penetration but is not recommended owing to inferior efficacy.

[e]Penetration often inadequate even when the meninges are inflamed.

The aminoglycosides have a low therapeutic index, and adequate CSF concentrations are difficult to achieve with IV dosing alone without risking significant toxicity. Thus, when aminoglycoside therapy is initiated for adults with CNS infections, concomitant intrathecal therapy is usually required. Similarly, the polymyxins are large hydrophilic compounds with substantial toxicity, and thus intrathecal administration is preferred.[28],[30]

Vancomycin is a large hydrophilic compound with moderate protein binding (50%) and as such does not diffuse well across the blood–CSF barrier. Therapeutic concentrations in the CSF (up to 30% of serum concentrations) may be attained with systemic vancomycin therapy when the meninges are inflamed. Other studies have found much lower penetration, however, and, as such, concomitant intraventricular therapy also may be necessary in selected circumstances.[28],[30] Consensus guidelines, which were revised in 2020, recommend targeting a vancomycin area under the curve over 24 hours to a minimum inhibitory concentration (AUC/MIC) of 400 to 600 when treating serious methicillin-resistant *Staphylococcus aureus* (MRSA) infections including meningitis.[33] However, as with trough targets espoused in a prior iteration of the guidelines, the optimal target AUC is not defined for this indication. Loading doses of 20 to 35 mg/kg should be strongly considered for patients with CNS infections.

Fluoroquinolones are moderately lipophilic, have a molecular weight of ~300 Da, and are not protein bound to a large extent. As would be expected, they penetrate reasonably well into the CSF on a percentage basis (~40%–60% or higher).[28],[30] Despite this, clinical data supporting the use of fluoroquinolones for bacterial CNS infections are lacking, although some hypotheses may be made. First, given its potent activity against *S. pneumoniae*, moxifloxacin may be an option for pneumococcal infections with limited therapeutic options, such as infections caused by penicillin- and ceftriaxone-resistant isolates.[34] Second, CSF concentrations attained are likely inadequate for infection caused by bacteria with higher

MICs (≥0.125–0.5 μg/mL, depending on the specific organism and drug).[35] This is especially relevant because concerns regarding CNS toxicity have generally limited the study and practice of nonstandard, increased fluoroquinolone dosages for bacterial CNS infections.[28,30] Finally, given the high rates of gram-negative resistance to fluoroquinolones, these agents should not be considered reliable as empiric therapy options in patients considered at risk for infections caused by such organisms.[36] Taken together, the fluoroquinolones are rarely utilized for the treatment of bacterial CNS infections.

Macrolides such as erythromycin and clarithromycin have a relatively high molecular weight and are substrates for a transporter that is abundant at the blood–brain barrier, P-glycoprotein. As such, they do not reach adequate concentrations when meningeal inflammation is lacking, and their lack of bactericidal activity further limits their utility in the treatment of bacterial meningitis. Bacteriostatic activity against *S. pneumoniae* also limits the utility of the tetracyclines and tigecycline. Clindamycin penetrates the CSF poorly and should not be used in the treatment of meningitis. Linezolid is also generally bacteriostatic, but because it often retains activity against multiresistant gram-positive pathogens and achieves CSF levels comparable to those in plasma, it may be considered an option for infections caused by gram-positive infections that are resistant or refractory to frontline options. Daptomycin is generally bactericidal and active against multiresistant gram-positive pathogens, but it is a large, highly protein-bound compound, and, thus, CSF penetration is low (≤10% of plasma levels). Use of higher doses and intrathecal administration is being actively explored, but current utility is limited.[28,30]

EMPIRIC THERAPY FOR CHILDHOOD MENINGITIS

Case 65-1, Question 3: A detailed medication and vaccination history reveals that S.C. and his brother appropriately received vaccination for Hib when they were 2 months old. What constitutes appropriate empiric therapy for childhood meningitis? Which antibiotic would be appropriate for S.C.? What dose and route of administration should be used?

Because results from culture and sensitivity testing of CSF will not be available for >24 hours, empiric therapy must be instituted promptly. The regimen should take into consideration the patient's age, any predisposing conditions, results from the CSF Gram stain, history of allergy, and the presence of organ dysfunction. **Table 65-5** gives recommendations for empiric antimicrobial therapy for acute bacterial meningitis.[11,37]

Table 65-5
Empiric Therapy for Bacterial Meningitis

Age Group or Predisposing Condition	Recommended Therapy	Alternative Therapy
Neonates (<1 month)	Ampicillin + cefotaxime	Ampicillin + gentamicin
Infants and children (1–23 months)	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Older children and adults (2–50 years)	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Elderly (>50 years)	Ampicillin, cefotaxime, or ceftriaxone + vancomycin	Vancomycin + TMP-SMX + aztreonam or vancomycin + meropenem
Postneurosurgical	Vancomycin + ceftazidime/cefepime	Vancomycin + meropenem
Closed head trauma	Cefotaxime or ceftriaxone + vancomycin	Vancomycin + aztreonam/meropenem
Penetrating head trauma	Vancomycin + ceftazidime/cefepime	Vancomycin + meropenem
Immunocompromised	Vancomycin + cefepime + ampicillin	Vancomycin + TMP-SMX + aztreonam or vancomycin + meropenem

TMP-SMX, trimethoprim–sulfamethoxazole.

S.C. is 5 years old and has a negative CSF Gram stain result. Therefore, therapy with a third-generation cephalosporin, such as

ceftriaxone or cefotaxime, is preferred. Either of these two agents will provide excellent coverage of the most likely pathogens in this age group (*S. pneumoniae* and *N. meningitidis*).[11,37] Of these two pathogens, S.C.'s rash suggests that *N. meningitidis* is likely.[38] *H. influenzae* is not very likely because he was vaccinated against Hib. Thus, initiation of ceftriaxone plus vancomycin would be appropriate for S.C. at this time.

Use of a cephalosporin in this case is appropriate despite the allergic history with amoxicillin (history of skin rash). Patients with a documented penicillin allergy carry an ~2% risk of cross-reactivity when cephalosporins are prescribed, depending on the agent. In this setting, the type of reaction to penicillin is important to consider. Patients with a history of accelerated hypersensitivity reactions (eg, hives, shortness of breath [SOB], or anaphylaxis) to penicillins should not be given cephalosporins in most instances. Conversely, a benign skin rash would not contraindicate use of a cephalosporin.[39] If S.C. had experienced an accelerated reaction to penicillin, vancomycin plus aztreonam, or meropenem would be the best alternative choice (Table 65-5).[11]

DOSING CONSIDERATIONS

In general, therapy for meningitis requires the use of high dosages of antimicrobials administered by the IV route. **Table 65-6** lists the recommended dosing regimens for the treatment of CNS infections. S.C. should receive ceftriaxone in a dosage of 100 mg/kg/day given in one or two doses. A ceftriaxone regimen of 1000 mg IV every 12 hours is reasonable for S.C.

Table 65-6
Suggested Antibiotic Dosing Regimens for Treatment of Central Nervous System Infections

Antibiotic	Daily Dose (interval in hours)[a]			
	Neonates 0–7 Days Old	Neonates 8–28 Days Old	Infants and Children	Adults
Ampicillin	150 mg/kg (8)	200 mg/kg (6–8)	300 mg/kg (6)	12 g (4)
Aztreonam				8 g (6)
Nafcillin	75 mg/kg (8–12)	100–150 mg/kg (6–8)	200 mg/kg (6)	12 g (4)
Penicillin G	0.15 mU/kg (8–12)	0.2 mU/kg (6–8)	0.3 mU/kg (4–6)	24 mU (4)
Meropenem			120 mg/kg (8)	6 g (8)
Cephalosporins				
Cefotaxime	100–150 mg/kg (8–12)	150–200 mg/kg (6–8)	225–300 mg/kg (6–8)	12 g (4)
Ceftriaxone			80–100 mg/kg (12–24)	4 g (12)
Ceftazidime	100–150 mg/kg (8–12)	150 mg/kg (8)	150 mg/kg (8)	6 g (8)
Cefepime			150 mg/kg (8)	6 g (8)
Aminoglycoside[b,c]				
Gentamicin	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5–7 mg/kg (8–24)
Tobramycin	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5–7 mg/kg (8–24)
Amikacin	15–20 mg/kg (12)	30 mg/kg (8)	20–30 mg/kg (8)	15 mg/kg (8–24)
Others				
Moxifloxacin				400 mg (24)
Linezolid				1200 mg (12)
Rifampin		10–20 mg/kg (12)	10–20 mg/kg (12–24)	600 mg (24)
TMP-SMX[d]			10–20 mg/kg (6–12)	10–20 mg/kg (6–12)
Vancomycin[c,e]	10–20 mg/kg (8–48) depending on postmenstrual age, weight, and serum creatinine	10–20 mg/kg (8–48) depending on postmenstrual age, weight, and serum creatinine	**Ages 1–3 months:** 10–20 mg/kg (8–48) **Ages 3 months to <12 years:** 60–80 mg/kg (6) **Ages ≥12 years:** 60–70 mg/kg (6–8)	30–60 mg/kg (8–12)

[a]Recommended daily dose when renal and hepatic functions are normal.

[b]Concurrent intraventricular doses of 5 to 10 mg (gentamicin, tobramycin) or 20 mg (amikacin) often required when treating gram-negative bacillary meningitis.

[c]Dose should be individualized based on serum level monitoring.

[d]Dose is based on the trimethoprim component.

[e]Concurrent intraventricular doses of 5 to 20 mg recommended if response to intravenous (IV) therapy is inadequate.

Therapeutic monitoring of vancomycin for serious methicillin-resistant Staphylococcus aureus infections: a revised consensus guideline and review by the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the Society of Infectious Diseases Pharmacists. *Am J Health Syst Pharm*. 2020;77(9):835–864.

ADJUNCTIVE CORTICOSTEROID THERAPY

Case 65-1, Question 4: What is the rationale for adjunctive corticosteroid therapy in acute bacterial meningitis, and would it be appropriate for S.C.? How should dexamethasone be dosed and monitored for S.C.?

Corticosteroids, particularly dexamethasone, can reduce cerebral edema and lower intracranial pressure.[40] In addition, corticosteroids reduce the synthesis and release of the proinflammatory cytokines tumor necrosis factor (TNF)-α and interleukin (IL)-1β from monocytes and astrocytes. These two cytokines play a central role in initiating the cascade of events that leads to neuronal tissue damage and neurologic sequelae.[41] Theoretically, then, inhibition of cytokine synthesis by corticosteroids in meningitis should lead to a decreased risk of hearing loss and other neurologic sequelae. Indeed, a prospective, randomized, double-blind multicenter trial evaluating the use of dexamethasone in adults with acute bacterial meningitis supported this theory.[42] A total of 301 patients were randomized to receive dexamethasone or placebo 15 to 20 minutes before or with the first dose of antibiotic every 6 hours for 4 days. Dexamethasone reduced the risk of an unfavorable outcome, defined as a Glasgow Outcome Scale score of 1 to 4 at 8 weeks (relative risk [RR], 0.59; *P* = .03), and of death (RR, 0.48; *P* = .04). When the outcomes were analyzed based on culture results, mortality reduction (14% vs 34%) and all unfavorable outcomes (26% vs 52%) were only seen with dexamethasone therapy in patients with meningitis caused by *S. pneumoniae*. Outcomes in patients with meningitis caused by organisms other than *S. pneumoniae* were independent of whether they received dexamethasone or not. Neither gastrointestinal (GI) bleeding nor other adverse effects were increased in the dexamethasone group.

In children, several studies have also evaluated the role of adjunctive dexamethasone therapy in bacterial meningitis. Some prospective placebo-controlled, randomized trials have demonstrated that adjunctive dexamethasone therapy significantly reduces audiologic and neurologic sequelae in children older than 2 months. *H. influenzae*, however, was the causative pathogen in most of these meningitis cases, whereas the number of children with

streptococcal and meningococcal meningitis in these trials was small.[2],[43]–[47] As previously mentioned, the number of Hib cases has decreased dramatically, making the data from these trials difficult to apply to the present day. More recently, of the 166 patients enrolled in a trial comparing dexamethasone to placebo, 35 and 26 cases were caused by *S. pneumoniae* and *N. meningitides*, respectively, in the treatment arm. Fewer audiologic and neurologic sequelae were observed in the dexamethasone-treated group compared with the placebo group, but the difference did not reach statistical significance.[48]

More recently, a 2015 Cochrane meta-analysis evaluated data from 25 randomized trials that included over 4000 children and adults. In the overall population, glucocorticoid administration did not significantly reduce mortality. However, glucocorticoids did reduce mortality in the subgroup of patients with meningitis caused by *S. pneumoniae* (RR, 0.84; 95% confidence interval [CI], 0.72–0.98). In studies conducted in high-income countries, glucocorticoids reduced severe hearing loss (RR, 0.51; 95% CI, 0.35–0.73), any hearing loss (RR, 0.58; 95% CI, 0.45–0.73), and short-term neurologic sequelae (RR, 0.64; 95% CI, 0.48–0.85). In the subgroup of over 2000 children, the administration of dexamethasone did not affect mortality but did reduce the incidence of severe hearing loss, particularly in those with *H. influenzae* meningitis.[49]

The 2004 Infectious Diseases Society of America (IDSA) meningitis guidelines recommend that dexamethasone be initiated before (or concomitant with the first dose of) antimicrobial therapy in all adult patients with suspected or proven pneumococcal meningitis.[11] Controversy remains over whether dexamethasone should be continued in adults if the causative agent is found not to be pneumococcus because the number of patients in the studies with meningitis caused by other organisms was small.[50] However, the guidelines do recommend discontinuing dexamethasone if the organism is found to be something other than *S. pneumonia*.[11] Regarding pediatrics, the American Academy of Pediatrics (AAP) Committee on Infectious Diseases suggests that dexamethasone therapy may be beneficial in children with Hib meningitis if given

before or at the same time as the first dose of antimicrobial therapy.[51] The AAP Committee on Infectious Diseases also suggests that the decision to use adjunctive dexamethasone therapy should be individualized but considered for infants and children older than 6 weeks with pneumococcal meningitis.[52] At this time, there can be no firm recommendation as to whether steroids should be continued in children if the pathogen is found not to be *H. influenzae* or *S. pneumoniae.*

Thus, S.C. should receive dexamethasone therapy, 0.15 mg/kg/dose given IV every 6 hours for 2 to 4 days. For S.C., who is 44.09 pounds (20 kg), this would be 3 mg every 6 hours, with the first dexamethasone dose given 15 minutes before initiating ceftriaxone therapy.

Potential adverse effects associated with dexamethasone include GI bleeding, mental status changes (eg, euphoria or encephalopathy), increases in blood glucose, and, possibly, elevations in blood pressure. For S.C., the complete blood count (CBC), serum chemistries, and stool guaiac should be monitored daily while he is receiving dexamethasone. He also should be questioned about possible GI upset and assessed for changes in mental status (eg, confusion, combativeness). Given the short duration of corticosteroid therapy, dexamethasone can be discontinued abruptly without tapering.

EFFECT ON CENTRAL NERVOUS SYSTEM PENETRATION OF ANTIBIOTICS

Another important issue to consider is whether dexamethasone, a potent anti-inflammatory agent, reduces the ability of antimicrobials to penetrate across the blood–brain barrier into CSF. Because CSF penetration of the penicillins, cephalosporins, and vancomycin is greatest when the meninges are inflamed, a hypothetical concern is that concomitant dexamethasone may reduce CSF concentrations of these agents, resulting in reduced efficacy. Early animal models suggest that vancomycin penetration into the CSF is reduced in dexamethasone-treated animals compared with animals not treated

with steroids.[53] In a rabbit meningitis model, the coadministration of dexamethasone and vancomycin resulted in 29% less penetration of vancomycin into the CSF. By increasing the daily dose of vancomycin in these rabbits, however, therapeutic CSF levels were achieved, suggesting that giving larger daily doses of vancomycin circumvents the steroid effect on CNS penetration.[54] In addition, current human data suggest that CSF penetration of vancomycin or ceftriaxone is not diminished with concomitant administration of dexamethasone.[55–58] Based on these encouraging findings, it is recommended that dexamethasone be utilized in all patients.[11]

Neisseria meningitidis Meningitis

DEFINITIVE THERAPY

Case 65-1, Question 5: Twenty-four hours after admission, S.C.'s culture results from his blood and CSF samples are available. The CSF culture is growing *N. meningitidis* (penicillin MIC, 0.06 mg/L), and *N. meningitidis* is also growing in both the collected blood cultures. What modification in S.C.'s antimicrobial therapy is necessary at this time?

Once culture and sensitivity results become available, definitive therapy can be instituted, often with a single agent (**Table 65-7**).[11,37] As suspected, S.C.'s CSF culture result is positive for *N. meningitidis.* Cefuroxime, a second-generation cephalosporin, has activity against *N. meningitides*; however, it is less effective for meningitis than are third-generation cephalosporins and should not be used.[59,60] The reason for the inferiority of cefuroxime relative to ceftriaxone most likely is related to reduced potency.[59]

Table 65-7
Definitive Therapy for Bacterial Meningitis

Pathogen	Recommended Treatment	Alternative Agents
Haemophilus influenza		

β-Lactamase negative	Ampicillin	Cefotaxime or ceftriaxone; aztreonam
β-Lactamase positive	Cefotaxime or ceftriaxone	Aztreonam
Neisseria meningitidis	Penicillin MIC <0.1 μg/mL: penicillin G or ampicillin	Cefotaxime or ceftriaxone; meropenem
	Penicillin MIC 0.1–1.0 μg/mL: cefotaxime or ceftriaxone	
Streptococcus pneumoniae	Penicillin MIC ≤0.06 μg/mL: penicillin G or ampicillin	Cefotaxime or ceftriaxone
	Penicillin MIC ≥0.12 μg/mL: cefotaxime or ceftriaxone if susceptible	Vancomycin or meropenem
	Penicillin and cefotaxime/ceftriaxone nonsusceptible: vancomycin + cefotaxime/ceftriaxone ± rifampin	Vancomycin + moxifloxacin
Streptococcus agalactiae	Penicillin G or ampicillin + gentamicin	Cefotaxime or ceftriaxone
Listeria monocytogenes	Penicillin G or ampicillin ± gentamicin	TMP-SMX or meropenem
Enterobacteriaceae		
Escherichia coli, Klebsiella species	Cefotaxime or ceftriaxone	Cefepime; aztreonam; meropenem
Enterobacter, *Serratia* species	Cefepime; meropenem	TMP-SMX; aztreonam
Pseudomonas aeruginosa	Cefepime or ceftazidime; meropenem	Aztreonam
Staphylococcus aureus[a]		
Methicillin-susceptible (MSSA)	Nafcillin or oxacillin	Vancomycin ± rifampin; meropenem
Methicillin-resistant (MRSA)	Vancomycin ± rifampin	TMP-SMX; linezolid
Staphylococcus	Vancomycin ± rifampin	TMP-SMX;

epidermidis[a]		linezolid

MIC, minimum inhibitory concentration; TMP-SMX, trimethoprim–sulfamethoxazole.

[a]Concomitant intrathecal therapy may be required for optimal response (most commonly an intrathecal aminoglycoside for gram-negative or intrathecal vancomycin for gram-positive infections).

Because *N. meningitidis* is susceptible to penicillin and ampicillin currently, penicillin is the drug of choice. However, S.C.'s questionable history of amoxicillin rash makes the use of ceftriaxone a reasonable choice (see Table 65-6 for dosing).

MONITORING THERAPY

Case 65-1, Question 6: What subjective and objective data should be monitored to evaluate the efficacy and toxicity of treatment of patients with meningitis, and what specifically should be monitored in S.C.?

Clinical signs and symptoms attributable to the disease, such as fever, altered mental status, and stiff neck, should be checked periodically throughout the day and monitored for resolution. S.C.'s temperature and mental status should be assessed often. Accurate assessment of S.C.'s mental status can be difficult because of his young age. Thus, his baseline level of mental status should be evaluated (eg, whether he is awake and alert, or lethargic and difficult to arouse). If awake and alert, S.C. should be observed for irritability, because this often is the only sign of altered mentation. Questions can be used to assess his orientation: Does he know where he is? Does he know his name? Can he recognize his mother or other family members? In general, signs of clinical improvement should be evident within 24 to 48 hours in most uncomplicated cases of acute bacterial meningitis, with defervescence of fever achieved in a mean of 3.3 days in one trial of cefotaxime in children.[61]

Laboratory tests should be monitored as well. A CBC with differential, serum electrolytes (eg, Na^+, K^+, Cl^-, HCO_3^-), blood glucose, and renal function tests (eg, BUN, SCr) should be

performed daily. Abnormal electrolyte results may require more frequent monitoring. Laboratory abnormalities, such as leukocytosis and hyponatremia, may take longer to normalize than do clinical symptoms. CSF chemistries usually improve within 48 hours of starting therapy, although CSF WBC and protein may remain elevated for a week or more.[62,63] With effective therapy, the CSF culture usually is sterile after about 18 to 24 hours of therapy.[59,61] Delays in CSF sterilization are associated with a higher propensity for neurologic complications.[59] If S.C. responds to therapy in a straightforward manner, he need not have a repeat lumbar puncture. If the response is inadequate, as evidenced by persistent fever or deteriorating mental status, S.C. will require a repeat lumbar puncture to reexamine the CSF parameters.[11]

In addition to monitoring the therapeutic response, side effects of the antimicrobial regimen also need to be assessed frequently. Meningitis requires high-dose therapy, making the likelihood of adverse effects much greater. Currently, S.C. is being treated with ceftriaxone. The adverse effects most often associated with ceftriaxone include hypersensitivity reactions, mild pain and phlebitis at the injection site, and GI problems.[64] S.C. should be observed for the formation of an antibiotic-related skin rash or evidence of an accelerated allergic reaction (eg, hives, wheezing). The IV catheter site should be observed daily for redness, tenderness, or pain on palpation of the vein. S.C. should be watched closely for loose stools or diarrhea. Although mild diarrhea is a common side effect of most antimicrobials that rarely requires a change in therapy, diarrhea that is severe, persistent, or accompanied by fever, unexplained leukocytosis, or abdominal cramping should prompt testing for *Clostridium difficile* colitis.[60,65]

CEFTRIAXONE-INDUCED BILIARY PSEUDOLITHIASIS

Case 65-1, Question 7: After 5 days of treatment, the nurse caring for S.C. notes that his appetite is markedly diminished, and he has an upset stomach. S.C. was afebrile and alert and oriented, but abdominal examination revealed

"guarding," with pain localized in the right upper quadrant area. Laboratory data at this time are as follows:

WBC count, 6000 cells/μL
Hgb, 12.5 g/dL
Hct, 34%
Platelets, 120,000/μL
Na, 135 mEq/L
K, 3.6 mEq/L
Cl, 98 mEq/L
Aspartate aminotransferase (AST), 35 units/L
Alanine aminotransferase (ALT), 33 units/L
Alkaline phosphatase, 110 IU/dL
Total bilirubin, 1.2 mg/dL
Amylase, 70 units/L

A stool guaiac test result is negative. What are the possible causes of S.C.'s abdominal discomfort?

A number of possible causes exist for S.C.'s abdominal discomfort. His corticosteroid therapy may have caused acute GI bleeding; however, the dexamethasone was discontinued 3 days ago and S.C.'s hemoglobin and hematocrit values are in the low-normal range. The negative stool guaiac result also argues strongly against a GI bleed. Acute pancreatitis is unlikely given the normal amylase result. Viral or drug-induced hepatitis is another possibility but also is unlikely given his normal AST, ALT, and bilirubin results. An intra-abdominal infection also is possible, but this is improbable because he is afebrile and has a normal WBC count. Other causes, such as acute cholecystitis or appendicitis, require further diagnostic evaluation.

Case 65-1, Question 8: An abdominal ultrasound reveals sludge in the gallbladder. What is the significance of this finding in S.C., and how should this abnormality be managed?

The abnormality on S.C.'s abdominal ultrasound explains his right upper quadrant pain. S.C. has what appears to be a condition known as biliary pseudolithiasis (ie, biliary "sludging"). Biliary sludging can occur under conditions of gallbladder hypomotility (eg, recent

surgery, burns, total parenteral nutrition) and, in some instances, can be drug induced. S.C. has been receiving ceftriaxone for treatment of his meningitis, and this drug can cause biliary pseudolithiasis.[66]

Antibiotic-associated biliary pseudolithiasis is seen almost exclusively with ceftriaxone. The biliary excretion associated with ceftriaxone results in very high concentrations of the drug in gallbladder bile. In selected circumstances, the biliary concentration of ceftriaxone may exceed solubility limits, resulting in the formation of a fine, granular precipitate (ie, sludge), which differs in composition and ultrasound features from true gallstones. The precipitate is composed of a ceftriaxone–calcium complex, the formation of which is dose dependent. Given the high dosages required for meningitis therapy, it is not surprising that this adverse effect has occurred in S.C.[66] In the comparative randomized trial between ceftriaxone and cefuroxime cited previously, evidence of biliary pseudolithiasis on abdominal ultrasonography was observed in 16 of 35 (46%) patients who received ceftriaxone and in none of 35 patients receiving cefuroxime.[59] Pseudolithiasis usually appears 3 to 10 days following the start of therapy and, in most instances, it is clinically asymptomatic. Symptoms similar to acute cholecystitis are evident in some individuals and include nausea with or without vomiting and abdominal right upper quadrant pain.[66]

Prompt recognition of this adverse effect and discontinuation of ceftriaxone therapy are required to effectively manage biliary pseudolithiasis. Once S.C.'s ceftriaxone is discontinued, the condition should resolve gradually over a period of weeks to months; the clinical symptoms should disappear within a few days.[66] Cefotaxime can be substituted for ceftriaxone; cefotaxime is not associated with biliary complications, and the efficacy of these two agents is equivalent.[64] For S.C., the cefotaxime dosage would be 1000 mg IV every 6 hours (Table 65-6).

DURATION OF THERAPY

CASE 65-1, QUESTION 9: What is the recommended duration of antimicrobial therapy for S.C.?

The optimal duration of therapy for meningitis is difficult to ascertain because few trials have been designed to address this issue.[67] Although general guidelines exist, the duration should be individualized based on the response to therapy, the presence of complicating factors (eg, immunosuppression), and the specific causative pathogen. **Table 65-8** lists the recommended treatment durations for uncomplicated cases of bacterial meningitis according to the specific pathogen. Patients such as S.C. with meningitis caused by *N. meningitidis* should be treated for 7 days.[11] Complicated cases, such as those with delayed CSF sterilization, require therapy for longer periods (up to 2 weeks or more).

Table 65-8
Duration of Therapy for Bacterial Meningitis

Etiology	Duration of Therapy (days)
Haemophilus influenzae	7
Neisseria meningitidis	7
Streptococcus pneumoniae	10–14
Group B streptococci *(Streptococcus agalactiae)*	14–21
Listeria monocytogenes	≥21
Gram-negative bacilli	21

PREVENTION OF NEISSERIA MENINGITIDIS MENINGITIS

CASE 65-1, QUESTION 10: S.C. is ready to be discharged home. How can the potential spread of meningococcal disease be prevented in persons with whom S.C. has contact?

Despite an excellent response to therapy, S.C. still may harbor *N. meningitidis* in his nasopharynx and could transmit this organism to individuals with whom he has close contact.[18],[68],[69] Therefore,

chemoprophylaxis to prevent secondary cases of *N. meningitidis* is indicated for S.C. and his close contacts. In this context, close contacts include the following: a household member including roommates and young adults in dormitories, child care center contacts, and any person directly exposed to the patient's oral secretions (eg, through kissing, mouth-to-mouth resuscitation, or endotracheal intubation) in the 7 days before symptom onset and until 24 hours after initiation of appropriate antibiotics.[68,70] Health care personnel and any passenger on a flight who had direct contact with respiratory secretions or anyone seated directly next to an index patient on a prolonged flight (eg, one lasting ≥8 hours) should also receive chemoprophylaxis.[70]

S.C.'s 7-year-old brother, the children at the day care center, and close contacts at the hospital who have been caring for S.C. are at risk for invasive *N. meningitidis* disease and should receive chemoprophylaxis. Because the risk of secondary disease is greatest immediately after onset of disease in the index patient, chemoprophylaxis should be instituted as soon as possible and ideally within 24 hours.[68] Administering chemoprophylaxis ≥14 days after identification of the index case is of little value. Regimens to reduce nasopharyngeal carriage of *N. meningitidis* include rifampin, ciprofloxacin, and ceftriaxone. The most frequently used regimen for children 1 month or older is rifampin, given every 12 hours in a dosage of 10 mg/kg/dose for 2 days. For adults, rifampin given every 12 hours in a dosage of 600 mg for 2 days is commonly used. The index patient should also receive prophylaxis if they were treated with an agent other than a third-generation cephalosporin as soon as he/she is able to tolerate oral medications and before being discharged from the hospital.[70]

Because S.C. is receiving ceftriaxone, he does not need chemoprophylaxis. S.C.'s brother, parents, and day care contacts should be treated with appropriate doses of rifampin as soon as he is diagnosed. Because rifampin is not recommended for pregnant females, ceftriaxone would be a viable alternative.

Streptococcus pneumoniae Meningitis

CLINICAL FEATURES, PREDISPOSING FACTORS, AND DIAGNOSIS

CASE 65-2

QUESTION 1: A.L., a 58-year-old male with a long history of alcohol abuse, is admitted to the ED febrile and unresponsive. During the past several days, A.L. has experienced intermittent episodes of fever, chills, SOB, and a worsening productive cough. A friend visiting A.L. called 911 when he could not arouse him. A.L.'s medical records indicate that he has hypertension, adult-onset diabetes mellitus, peptic ulcer disease (PUD), and chronic obstructive pulmonary disease (COPD). A splenectomy was performed 10 years ago after trauma to the abdomen. A.L. is divorced and lives alone in a low-income apartment. He has no known drug allergies. His records show him to be a smoker for >30 years. Current medications include hydrochlorothiazide 50 mg every other day, glipizide 5 mg orally (PO) twice daily, famotidine 20 mg PO every day at bedtime, and doxycycline PO twice daily as needed for cough and increased sputum production.

On admission to the ED, A.L. had a temperature of 104 °F (40 °C), blood pressure of 90/50 mm Hg, and pulse and respiratory rates of 115 beats/minute and 25 breaths/minute, respectively. His weight is 130.07 pounds (59 kg). A.L. was unresponsive but withdrew all extremities to painful stimuli. His pupils were equal and sluggishly reactive to light; papilledema and evidence of meningismus were present. Wheezes and crackles were heard throughout both lung fields, with dense consolidation noted in the left lower lobe. The remainder of his physical examination was noncontributory.

Stat laboratory tests revealed the following:

WBC count, 18,000 cells/μL, with 80% PMN, 15% bands, 3% lymphocytes, and 2% basophils
Hgb, 10.5 g/dL
Hct, 34%
Platelet count, 250,000/μL
K, 3.0 mEq/L
Glucose, 250 mg/dL
AST, 190 mg/dL
ALT, 140 mg/dL
BUN, 35 mg/dL
SCr, 2.4 mg/dL

The prothrombin time was high normal, and albumin was 3.1 mg/dL. A STAT blood alcohol level of 100 mg/dL was reported, and a urine toxicology screen

result was negative. A.L.'s serum theophylline concentration was 18 mg/dL. Stool guaiac test result was positive.

A CT scan showed no evidence of mass lesions or cerebral hematoma. Lumbar puncture yielded the following results:

CSF opening pressure, 200 mm Hg
Protein, 120 mg/dL
Glucose, 100 mg/dL
WBC count, 8500 cells/μL, with 92% PMN, 4% monohistiocytes, and 4% lymphocytes
RBC count, 400/μL

Gram-positive, lancet-shaped diplococci were visible on CSF Gram stain. In addition, a sputum Gram stain test revealed numerous WBCs, few epithelial cells, and numerous gram-positive cocci in pairs and in short chains. Blood, CSF, urine, and sputum culture results are pending.

What are the clinical and laboratory features of pneumococcal meningitis? What features of pneumococcal meningitis are present in A.L.?

A.L. presents to the ED with many signs and symptoms suggestive of pneumococcal meningitis. He is 56 years old, and *S. pneumoniae* is the most common bacterial etiology for meningitis in adults age older than 30 years (Table 65-1). As is evidenced by A.L.'s presentation, invasive pneumococcal disease often is associated with significant morbidity, and mortality rates remain high.[1] However, likely due to the introduction of conjugate vaccines, the incidence of *S. pneumoniae* meningitis in the United States has significantly decreased, from 0.8 cases per 100,000 people in 1997 to 0.3/100,000 in 2010.[71] Predisposing factors to invasive pneumococcal disease include advanced age, cigarette smoking, alcoholism, diabetes, chronic pulmonary disease, and functional (sickle cell disease) or anatomic (splenectomy) asplenia. In addition, individuals infected with the human immunodeficiency virus (HIV) or with other immunocompromising conditions (such as solid organ or bone marrow transplantation) are at higher risk. Patients with CSF otorrhea or rhinorrhea induced by closed head trauma or neurosurgical procedures are more susceptible to develop pneumococcal meningitis as well.[72]

A.L. has many predisposing factors for pneumococcal meningitis. He smokes, has a long history of alcohol abuse, has had a

splenectomy, and has diabetes and COPD. A diagnosis of pneumococcal meningitis in A.L. is supported by the high fever, stiff neck (meningismus), and altered mental status. He is unresponsive, which is a definite negative prognostic factor.[73] Results from CSF chemistries and microbiologic analysis are highly suggestive of pneumococcal meningitis. A.L. has an elevated opening CSF pressure and a markedly elevated CSF protein and WBC count with a predominance of neutrophils on differential examination. The normal CSF glucose level (100 g/dL) is misleading because A.L. is diabetic. The calculated ratio of CSF to serum glucose for A.L. is <50%, which is consistent with acute bacterial meningitis (Table 65-3). The presence of gram-positive, lancet-shaped diplococci in pairs on the CSF Gram stain result strongly supports the diagnosis of pneumococcal disease. The signs and symptoms of pneumococcal pneumonia (cough, SOB, increased sputum production, and pulmonary consolidation) as well as the sputum Gram stain result also lend support to a diagnosis of invasive pneumococcal infection.

EMPIRIC THERAPY IN ADULTS

CASE 65-2, QUESTION 2: What would be appropriate therapy for A.L.?

Table 65-7 provides therapy recommendations for pneumococcal meningitis based on penicillin and ceftriaxone/cefotaxime susceptibility. Resistance among pneumococci to penicillin G (MIC ≥0.12 μg/mL) is a significant concern. In a surveillance study from 2006 to 2007, 27.5% of *S. pneumoniae* isolates from patients with meningitis were resistant to penicillin.[74] *S. pneumoniae* strains in CSF with MIC >0.5 μg/mL to cefotaxime or ceftriaxone are intermediate (1 μg/mL) or resistant (≥2 μg/mL). Reduced activity of ceftriaxone and cefotaxime against penicillin-resistant pneumococci affects the therapeutic ratio achieved in CSF and has been associated with clinical failure. Optimal therapy for fully penicillin-resistant pneumococcal meningitis should include vancomycin. The combination of vancomycin and ceftriaxone was superior to either

agent given alone in a rabbit model of penicillin-resistant pneumococcal meningitis. Ceftriaxone or vancomycin combined with rifampin also may be superior to either drug given alone.[75] With its potent pneumococcal activity and satisfactory CNS penetration, moxifloxacin may be an option for pneumococcal meningitis caused by penicillin- and ceftriaxone-resistant isolates.[34] However, clinical data supporting the use of moxifloxacin in this scenario are lacking. Thus, until more information is available, the combination of ceftriaxone or cefotaxime with vancomycin represents the most reasonable approach to empiric therapy for potential penicillin-resistant pneumococcal meningitis.

Until culture and susceptibility results are available, the recommended antibiotic in this situation is ceftriaxone 2 g given IV every 12 hours and vancomycin 30 to 60 mg/kg/day IV divided every 8 to 12 hours. A.L. weighs 130.07 pounds (59 kg), and because his renal function is not normal (SCr, 2.4 mg/dL; creatinine clearance, 30 mL/minute), a dosage adjustment was made.

CORTICOSTEROID THERAPY FOR ADULT MENINGITIS

CASE 65-2, QUESTION 3: Should A.L. receive corticosteroid therapy in addition to his antibiotic therapy?

A.L. presents with profoundly altered mental status, and his signs and symptoms are consistent with a fulminant course of disease. His age, underlying medical problems, likely streptococcal meningitis, and deteriorating clinical status all point to a poor prognosis and argue for the use of adjunctive dexamethasone. On the other hand, A.L. is diabetic and has an elevated glucose concentration. He also has PUD, which may be active given that he is anemic and has a positive stool guaiac result. High-dose dexamethasone therapy may impact on his mental status, making assessment even more difficult. Although each of these issues is a concern, none is so critical as to preclude the use of corticosteroids. Therefore, dexamethasone given in a dosage of 10 mg IV every 6 hours could be instituted before

starting ceftriaxone therapy provided that the diagnosis of bacterial meningitis is confirmed. Dexamethasone can be continued for up to 4 days if *S. pneumoniae* is found to be the causative pathogen. Dexamethasone may be discontinued if *S. pneumoniae* is not the causative pathogen.[11] To control blood glucose, a sliding scale dosing schedule of regular insulin is recommended. A.L.'s PUD should be properly worked up and treated if necessary.

TREATMENT OF PENICILLIN-SUSCEPTIBLE PNEUMOCOCCAL MENINGITIS

Case 65-2, Question 4: Results from A.L.'s CSF, blood, and sputum cultures are available and are positive for *S. pneumoniae* at each site. Sensitivity testing in CSF revealed an MIC of 0.06 µg/mL to penicillin, 0.25 µg/mL to cefotaxime and ceftriaxone, and 0.25 µg/mL to vancomycin. What therapy is indicated for A.L.?

A.L. is infected with a strain of *S. pneumoniae* that is susceptible to penicillin G (see Table 65-7).[76] The dosage usually is 24 million units/day in adults with normal renal function (see Table 65-6). A.L. has renal impairment, however, which means he should receive a reduced penicillin dosage. For A.L., who has a calculated creatinine clearance of ~28 mL/minute (according to the method of Cockcroft and Gault), the daily dose would be 12 to 16 million units, or 3 to 4 million units every 6 hours. This revised regimen should provide penicillin serum concentrations similar to those achieved with high-dose therapy when kidney function is normal. Failure to adjust the dosage appropriately is equivalent to providing excessive doses of penicillin, and seizures may result.[77] In patients unable to tolerate penicillin G, the best alternatives are ceftriaxone or cefotaxime (Table 65-7).[11,37]

Gram-Negative Bacillary Meningitis

CASE 65-3

QUESTION 1: R.R., a 40-year-old, 176.37-pound (80-kg) male, is admitted to the hospital for a cervical laminectomy with vertebral fusion. His surgical procedure was complicated by a dural tear. On the third postoperative day, drainage at his surgical excision site was noted, and R.R. was febrile to 100.76 °F (38.2 °C). The result of the Gram stain of the drainage revealed moderate gram-negative bacilli. Therapy with IV cefazolin 2 g every 8 hours was begun. The following morning, R.R. was oriented to person, place, and time, but he was slightly obtunded and had a temperature of 104 °F (40 °C). Neck stiffness could not be assessed because of his recent surgery. A magnetic resonance imaging (MRI) scan of the head and neck returned a negative finding, and lumbar puncture yielded the following CSF results:

WBC count, 3000 cells/μL, with 95% PMN
Glucose, 20 mg/dL
Protein, 280 mg/dL

What important clinical and laboratory features of gram-negative bacillary meningitis are manifested in R.R.?

EPIDEMIOLOGY

R.R. has developed gram-negative meningitis as a complication of his recent neurosurgical procedure. In the 2017 IDSA guidelines for health care–associated ventriculitis and meningitis, postneurosurgical CNS infections are classified as health care–associated ventriculitis and meningitis.[78] Gram-negative organisms are important pathogens particularly after neurosurgical procedures such as craniotomy.[71] Historically, mortality rates from gram-negative bacillary meningitis have been extremely high, ranging from 40% to 70%. With the availability of third-generation cephalosporins, some studies report that fatalities have declined to <40%; however, a recent study of 40 adults with spontaneous gram-negative meningitis reported a mortality rate of 53%.[79] Increasing resistance among certain gram-negative bacilli, such as *Enterobacter* species and *P. aeruginosa*, presents a therapeutic dilemma in that mortality associated with these pathogens is high and therapeutic options are fewer.

PREDISPOSING FACTORS

Individuals at greatest risk for gram-negative bacillary meningitis include neonates, the elderly, patients with underlying conditions such as diabetes mellitus or malignancy, patients with open trauma to the head, and individuals such as R.R. undergoing neurosurgical procedures.[78],[80] Although meningitis is a rare complication of clean neurosurgical procedures (eg, craniotomy, laminectomy), the consequences can be devastating when it does happen.[79]

MICROBIOLOGY

E. coli and *K. pneumoniae* have historically been the most common gram-negative bacteria causing meningitis; however, rates of pseudomonal meningitis appear to be increasing.[79],[81] *E. coli* is the most common gram-negative cause of neonatal meningitis, whereas *K. pneumoniae* is isolated more often in the elderly population.[82],[83] The remaining cases are generally divided evenly among *Proteus*, *Serratia*, *Enterobacte*r, *Citrobacter*, *Pseudomonas*, and other less common bacilli.[79]

CLINICAL FEATURES

In general, clinical laboratory features of gram-negative bacillary meningitis are similar to that of other types of bacterial meningitis.[1],[11] Because of high virulence, gram-negative bacillary meningitis often is a fulminant, rapidly progressive disease. An exception to this rule is meningitis after neurosurgery.[83] As is evidenced by R.R.'s clinical presentation, postneurosurgical gram-negative bacillary meningitis can present in a more subtle manner. In such patients, many of the symptoms of meningitis (eg, altered mental status, stiff neck) are masked by underlying neurologic disease. Thus, a high index of suspicion is warranted in the postsurgical setting. In addition to gram-negative bacilli, staphylococci also are associated with postneurosurgical meningitis.[78],[84]

TREATMENT OF GRAM-NEGATIVE BACILLARY MENINGITIS

Case 65-3, Question 2: What empiric therapy is appropriate for R.R. at this time?

Fewer choices are available for the treatment of gram-negative bacillary meningitis than for other meningitides. Ampicillin is active against only *E. coli*, *P. mirabilis*, and *Salmonella* species, but resistance has essentially eliminated its use. Aminoglycosides are limited by their inability to achieve therapeutic CSF concentrations, as well as reduced activity in the acidic milieu of purulent CSF.[85] Intraventricular administration, which results in therapeutic CSF concentrations, is usually reserved for difficult-to-eradicate shunt infections in combination with IV therapy because of the absence of data supporting their use.[21,44] As such, the 2017 IDSA guidelines recommend that intraventricular antimicrobials considered for the treatment of health care–associated ventriculitis and meningitis that responds poorly to systemic antimicrobials alone.[78] Unlike intraventricular administration, intralumbar injections will not result in therapeutic CSF concentrations in the ventricle.[44]

Health care–associated meningitis and ventriculitis include infections associated with CSF shunts or drains, intrathecal drug therapy such as baclofen infusions, deep brain stimulation hardware, and neurosurgery or head trauma.[78] Empiric antimicrobial regimens should include an agent with activity against *P. aeruginosa* and vancomycin in patients with health care–associated meningitis and ventriculitis. Because R.R. recently had a neurosurgical procedure, his empiric therapy should include an antipseudomonal agent such as cefepime, ceftazidime, or meropenem (see Table 65-5).[11] Because his surgical incision Gram stain revealed gram-negative bacilli, vancomycin may be withheld. Cefepime has excellent activity against *E. coli* and *K. pneumoniae* and is active against other enteric gram-negative bacilli as well (see Table 65-7).[32] Resistance to third-generation cephalosporins among *Enterobacter*, *Citrobacter*, and *Serratia* is so prevalent that these agents cannot be relied on for the treatment of meningitis caused by these pathogens.[86] With this in mind, therapy of gram-negative meningitis in situations where third-

generation cephalosporin resistance is likely (eg, nosocomial or postneurosurgical meningitis) should result in the use of cefepime or meropenem. If a pathogen is isolated, therapy may be tailored based on culture results, antibiotic sensitivities, and antibiotic penetration into the CNS. For example, success rates exceed 80% with cefotaxime and ceftriaxone for gram-negative bacillary meningitis caused by *E. coli* or *K. pneumoniae*.[87],[88] For R.R., cefazolin should be discontinued, and treatment with cefepime (2 g IV every 8 hours) should be instituted until the return of culture and sensitivity results.

TREATMENT OF ENTEROBACTER MENINGITIS

CASE 65-3, QUESTION 3: Culture results from R.R.'s wound drainage and CSF are both positive for *Enterobacter cloacae.* Sensitivity data reveal resistance to ceftriaxone, cefepime, ceftazidime, piperacillin–tazobactam, and aztreonam. Drugs to which the isolate is sensitive include imipenem, meropenem, TMP-SMX, gentamicin, tobramycin, and ciprofloxacin. What alteration in antimicrobial therapy is most appropriate for R.R. at this time?

Treatment of meningitis caused by *Enterobacter* and related species (eg, *Serratia*, *Citrobacter* species) presents a particular challenge.[32],[89] Furthermore, some isolates that are sensitive to third-generation cephalosporins can become resistant during therapy by virtue of selecting for derepressed mutants.[90] Thus, in contrast to gram-negative bacillary meningitis caused by *E. coli* and *Klebsiella* species, alternative therapies are needed when treating meningitis caused by *Enterobacter*, *Serratia*, *Citrobacter*, and *Pseudomonas* species. The isolate is sensitive to imipenem, but the higher propensity for seizures compared with other β-lactams (including penicillin G) argues against its use in R.R.[39] Meropenem is not considered to be epileptogenic and should be used preferentially to imipenem for meningitis.[91] Clinical trials have evaluated the efficacy and safety of meropenem versus cefotaxime in the treatment of meningitis in children. Clinical outcomes were similar among the patients randomized to either group, and the incidence of seizures was similar in the treatment groups.[92],[93] Thus, after consideration of

the aforementioned options, meropenem appears to be the best choice of therapy for R.R. and carries U.S. Food and Drug Administration (FDA) approval for this indication; however, TMP-SMX, although not FDA approved, may be an option as well.[94] Cefepime should be discontinued and, if confirmed to be susceptible, therapy started with meropenem 2 g IV every 8 hours adjusted for renal insufficiency.

DURATION OF THERAPY

The 2017 IDSA guidelines recommend a duration of 10 to 14 days for the treatment of health care–associated meningitis and ventriculitis caused by gram-negative bacilli, with some experts recommending longer courses of 21 days. Because of the high mortality and morbidity associated with these pathogens and the reduced susceptibility of enteric pathogens to antimicrobial agents, 21 days has been suggested by some experts. R.R. should be provided with at least 10 to 14 days of therapy (see Table 65-8).[11]

Staphylococcus epidermidis Meningitis or Ventriculitis

CLINICAL PRESENTATION OF CEREBROSPINAL FLUID SHUNT INFECTIONS

CASE 65-4

Question 1: T.A., a 21-year-old female with a history of congenital hydrocephalus, is admitted to the neurosurgery unit for worsening mental status and fever. T.A. has a history of multiple revisions and placements of intraventricular shunts for control of hydrocephalus. Currently, she has a ventriculoperitoneal (VP) shunt, which was placed 1 month ago and previously had been functioning normally. During the past few days, T.A. has exhibited worsening obtundation, stiff neck, and a temperature of 103.1 °F (39.5 °C). A CT scan performed today reveals enlarged ventricles consistent with acute hydrocephalus.

T.A.'s medical history is noncontributory except for a seizure disorder for which she takes phenytoin 400 mg PO at bedtime. She also takes Lo-Ovral® as

an oral contraceptive. T.A. is allergic to sulfa drugs (severe skin rash). Her weight on admission is 132.28 pounds (60 kg).

Laboratory analysis was significant for the following:

WBC count, 14,000 cells/μL, with a differential of 85% PMNs and 10% lymphocytes
BUN, 19 mg/dL
SCr, 0.9 mg/dL

A tap of T.A.'s shunt was performed, and the ventricular fluid was notable for the following results:

Total protein, 150 mg/dL
Glucose, 40 mg/dL
WBC count, 200 cells/μL, with 85% PMNs and 10% lymphocytes

The result of the Gram stain of the ventricular fluid showed numerous gram-positive cocci in clusters.

What are the subjective and objective findings of CSF shunt infections, and what manifestations of this type of infection are present in T.A.?

T.A. likely has health care–associated meningitis with ventriculitis secondary to infection of her VP shunt. The most important way to manage hydrocephalus involves the use of devices that divert (shunt) CSF from the cerebral ventricles to other areas of the body such as the peritoneum (VP shunts) or atrium (ventriculoatrial shunts).[95] This approach alleviates increased CSF pressure and substantially reduces morbidity and mortality.[96] Infection of these devices, however, is a common cause of shunt malfunction, as seen in T.A. The reported incidence of CSF shunt infections in children is ~11% in recent studies and varies in adults from 2.5% to 15% depending on patient factors, surgical technique, and the type and duration of the procedure performed (ie, shunt revision vs placement of a new device).[97–99] T.A., who has been hydrocephalic since birth and has a history of multiple shunt procedures, is at high risk for such an infection.

Clinical symptoms associated with infected CSF shunts vary widely from asymptomatic colonization to fulminant ventriculitis with meningitis. Fever is common and, in many instances, is the only presenting symptom. CSF findings also are slightly different in shunt infection compared with acute meningitis: The WBC count usually is

not as elevated, the decrease in CSF glucose is less pronounced, and the protein value may be normal or slightly elevated. CSF culture result is positive in most patients.[100] T.A.'s clinical presentation, CSF findings, and radiographic evidence of hydrocephalus are highly suggestive of a VP shunt infection. She is febrile and has altered mental status. The presence of a stiff neck strongly suggests meningeal involvement. Evaluation of T.A.'s ventricular fluid reveals a slightly elevated WBC count, with a predominance of PMNs, an elevated protein concentration, and a slightly lower than normal glucose concentration.

Skin microflora are the most common causes of CSF shunt infections. Coagulase-negative staphylococci (usually *Staphylococcus epidermidis*) account for roughly 50% of all cases and *S. aureus* accounts for roughly one-fourth of all cases. Other less common pathogens include diphtheroids, enterococci, and *Propionibacterium acnes*. Enteric gram-negative bacilli are responsible for a small percentage of cases; these cases usually occur when the distal end of the shunt is inserted improperly into the peritoneal cavity.[100,101] The gram-positive cocci in clusters on the Gram stain of T.A.'s CSF strongly suggest a staphylococcal shunt infection. Determining the coagulase status of the isolate will allow differentiation between *S. aureus* and coagulase-negative staphylococci, likely *S. epidermidis.*

TREATMENT OF CEREBROSPINAL FLUID SHUNT INFECTIONS

Case 65-4, Question 2: Culture and sensitivity tests of T.A.'s ventricular fluid are positive for *S. epidermidis.* The isolate is resistant to nafcillin but sensitive to vancomycin, rifampin, and TMP-SMX. How should T.A.'s CSF shunt infection be treated?

For T.A.'s CSF shunt infection to be optimally treated, a combined medical and surgical approach is required. Studies have demonstrated poorer outcomes for systemic antibiotic therapy alone versus systemic antibiotic therapy plus shunt removal.[102] Because many patients cannot tolerate the complete removal of their shunt for

long, externalization of the distal end of the shunt, or shunt removal and placement of an external drainage device, often is necessary during systemic antibiotic therapy.[78] The presence of an externalized device permits sequential sampling of ventricular fluid and also provides a convenient way to administer antibiotics intraventricularly (see the following discussion entitled Intraventricular Dosing of Vancomycin).

Glycocalyx

Although *S. epidermidis* is not as virulent a pathogen as *S. aureus*, it is extremely difficult to eradicate this organism from prosthetic devices such as CSF shunts. This is because many strains of *S. epidermidis* produce a mucous film or slime layer known as *glycocalyx*, which allows the staphylococci to adhere tightly to the shunt material, protecting them against phagocytosis.[99] As expected, antibiotic failures are much more likely with slime-producing strains of *S. epidermidis.*

Vancomycin is the drug of choice for treatment of shunt infections caused by *S. epidermidis* and should be instituted immediately in T.A.[11],[78] This is because a high percentage (>60%) of coagulase-negative staphylococci are resistant to methicillin (eg, methicillin-resistant *Staphylococcus epidermidis* [MRSE]). T.A.'s isolate also is sensitive to TMP-SMX, as is the case with many strains of MRSE (and also MRSA), but it must be avoided because T.A. is allergic to this drug combination. Although not considered a first-line therapy, linezolid has been shown to be effective for VP shunt infections in small case series and may be considered in patients who are allergic to vancomycin.[103],[104] In addition, many staphylococcal isolates (both *S. epidermidis* and *S. aureus*) are susceptible to rifampin, but monotherapy with this drug is not recommended because of rapid emergence of resistance. However, rifampin may be used in addition to an antistaphylococcal agent to enhance bactericidal activity, especially if the prosthesis is retained.[78]

Vancomycin therapy

CASE 65-4, QUESTION 3: What would be an appropriate IV dosage for vancomycin in T.A.? What subjective or objective data should be monitored to evaluate the efficacy and toxicity of the treatment?

Vancomycin therapy for T.A.'s CSF shunt infection requires the use of doses similar to those used for bacterial meningitis. For adults such as T.A., vancomycin dosages of 30 to 60 mg/kg/day have been endorsed.[11,33,78] For children ages 3 months to younger than 12 years with meningitis or infected shunts, the recommended dosage of vancomycin is 60 to 80 mg/kg/day, given IV in divided doses every 6 hours. For children ages 12 years and older, the recommended dosage of vancomycin is 60 to 70 mg/kg/day, given IV in divided doses every 6 to 8 hours (see Table 65-6).[33,78,105] An individualized target of the AUC/MIC ratio of 400 to 600 is recommended.[33] For neonates and infants up to 3 months of age, doses recommended to achieve an AUC of 400 range from 10 to 20 mg/kg every 8 to 48 hours, depending on postmenstrual age, weight, and serum creatinine.[11,33]

T.A., who weighs 132.28 pounds (60 kg), should be started on a vancomycin regimen of 1 g IV every 8 to 12 hours because her renal function is normal. In either case, trough serum concentrations should be obtained at steady state to assess whether the initial dosing regimen is adequate. Another consideration for T.A. is the addition of rifampin to her vancomycin regimen. This is based on the excellent staphylococcal activity of rifampin, its moderate CSF penetration, and the potential for synergy between these two agents.[106] Whether rifampin plus vancomycin is superior to vancomycin alone has not been determined. For T.A., it is best to avoid rifampin because evidence supporting its efficacy is weak, and she currently is taking phenytoin and oral contraceptives. Rifampin is a potent inducer of hepatic microsomal enzymes, which can lower serum phenytoin concentrations (possibly resulting in seizure activity) and increase the possibility of an unplanned pregnancy (from reduced effectiveness of the oral contraceptive pill).

Intraventricular Dosing of Vancomycin

Case 65-4, Question 4: Should T.A. receive intraventricular vancomycin? If so, what would be an appropriate dosage?

T.A. should receive IV vancomycin. In addition, T.A. has a long history of hydrocephalus and will require placement of an external drainage device after removal of her VP shunt. The external drainage device allows for intraventricular administration of vancomycin, and such treatment should be instituted promptly. Although dosage recommendations vary from 5 to 20 mg/day, most use 20 mg/day and this dose should be used for T.A. Also, serial (daily) cultures of CSF are recommended to monitor her response to therapy. Therapy should be continued for at least 10 days after sterilization of her ventricular fluid is documented, at which time a new VP shunt can be placed.[11]

In contrast to T.A.'s situation, vancomycin therapy for patients with MRSA meningitis not associated with a CSF shunt or indwelling ventricular catheter is more problematic. The 2017 IDSA guidelines endorse a 10- to 14-day course of IV vancomycin 30 to 60 mg/kg daily divided every 8 to 12 hours, with the potential addition of rifampin 600 mg daily. In addition, in seriously ill patients, including those with meningitis, a loading dose of 25 to 35 mg/kg of actual body weight may be considered. An individualized target of an AUC of 400 to 600 is recommended.[30] In the setting of drug allergy, intolerance, or adverse events, alternatives include linezolid 600 mg PO or IV every 12 hours, or TMP-SMX 5 mg/kg/dose IV every 8 to 12 hours.[107]

BRAIN ABSCESS

Epidemiology

Although not nearly as common as meningitis, abscesses of the brain parenchyma (brain abscess) remain an important type of CNS infection. The reported incidence of brain abscess caused by any type of organism ranges from 0.4 to 0.9 cases per 100,000 population.[108],[109] On a busy neurosurgical service, 4 to 10 cases a year typically are seen.[110],[111] For reasons that are not entirely clear, males are more likely to develop abscesses within the brain than are females.[109],[110] Brain abscess can occur at any age, but the mean age most recently reported is 34 years of age, with a minority of cases occurring in children.[112]

Despite advances in antimicrobial therapy over the past several decades, mortality rates from brain abscess have remained above 40% until recently. Developments in imaging techniques (eg, CT and MRI scanning), which allow early recognition of abscesses and the ability to serially monitor the radiographic response to antimicrobial therapy, have had the most profound impact on reducing morbidity and mortality from brain abscess. A meta-analysis of 123 studies found case fatality rates declined from 40% to 10% over the decades from 1970 to 2013, whereas the rates of full recovery increased from 33% to 70%. With the combined medical and surgical approach currently recommended, mortality rates continue to average <10%.[116]

Predisposing Factors

Brain abscesses most commonly arise from a contiguous suppurative source of infection (eg, sinusitis, otitis, mastoiditis, or dental infections).[112] The formation of a single abscess cavity usually is found when infection develops from a contiguous source. In addition, the abscess nearly always is formed in close proximity to the primary focus of infection (**Table 65-9**). For example, abscesses of sinusitic origin more commonly involve the frontal lobe, whereas otitic infections often lead to temporal lobe abscess formation.[113] Brain abscess also occurs as a consequence of hematogenous spread of organisms from a primary site of infection (eg, lung

abscess, endocarditis, osteomyelitis, pelvic, and intra-abdominal infections). Multiple abscesses suggest a metastatic source of infection. As with meningitis, brain abscess occurs as an infrequent complication of head trauma or neurosurgery.[116] No identifiable source (cryptogenic abscess) is detected in as many as 30% of cases.[113]

Table 65-9
Predisposing Conditions, Microbiology, and Recommended Therapy for Bacterial Brain Abscess

Predisposing Condition	Usual Location of Abscess	Most Likely Organisms	Recommended Therapy
Contiguous Site			
Otitis media	Temporal lobe or cerebellum	Streptococci (anaerobic and aerobic), *Bacteroides fragilis*, gram-negative bacilli	Ceftriaxone + metronidazole
Sinusitis	Frontal lobe	Streptococci (predominantly), *Bacteroides* species, gram-negative bacilli, *Staphylococcus aureus*, *Haemophilus* species	Vancomycin + ceftriaxone + metronidazole
Dental infection	Frontal lobe	*Fusobacterium* species, *Bacteroides* species, and streptococci	Ceftriaxone + metronidazole
Primary Infection			
Head trauma or neurosurgery	Related to the site of wound	Gram-negative bacilli, staphylococci, streptococci, *Clostridium*	Vancomycin + cefepime + metronidazole

Staging

Once an intracranial focus of infection is established, the evolution of brain abscess involves two distinct stages: cerebritis and capsule formation. The cerebritis stage evolves gradually over the first 9 to 10 days of infection and is characterized by an area of marked inflammatory infiltrate that contains a necrotic center surrounded by an area of cerebral edema. Capsule formation occurs about 10 to 14 days after the initiation of infection, and once formed, the capsule continues to thicken over a period of weeks. The stage of abscess development has important implications for therapy. Although it is best to wait until the capsule is fully formed before attempting any type of surgical intervention, antimicrobial therapy alone may resolve the infection if discovered in the early cerebritis stage.[114]

Microbiology

The microbiology of brain abscess is distinctly different from that of meningitis. Streptococci are implicated in 50% to 70% of cases and include anaerobic as well as microaerophilic streptococci of the *S. milleri* group.[112] Other anaerobes, particularly *Bacteroides* species (including *B. fragilis*) and *Prevotella* species, are the second most common cause of brain abscess and are usually in mixed culture.[110],[112] These organisms are followed by staphylococci and gram-negative bacteria as other common pathogens.[112] Although somewhat imprecise, a reasonable correlation exists between the various predisposing conditions and the microbiologic etiology of brain abscess (see Table 65-9).[113]

In the immunocompromised patient, a diverse group of microorganisms can induce abscesses within the brain. In patients with AIDS, *Toxoplasma gondii* is the most common infectious cause of focal brain lesions.[115] Transplant recipients and those receiving immunosuppressive therapy are susceptible to infection from *Nocardia* species and fungi (eg, *Aspergillus* or *Candida* species).[116] In Mexico and other Central American countries, cysticercosis remains a common cause of intracerebral infection.[117]

Clinical and Radiologic Features

CASE 65-5

Question 1: L.Y., a 40-year-old male, is brought to the ED by a friend. L.Y. reports severe headache, fever, weakness in his left arm and leg, and increasing drowsiness. During the past week, L.Y. has suffered from headaches, which have gradually worsened in intensity, and from intermittent episodes of fever. Despite getting plenty of sleep, L.Y. has been feeling increasingly drowsy during the past several days. When he noticed weakness in his left arm and difficulty concentrating this morning, he called a friend and asked to be taken in for evaluation.

L.Y. has a history of chronic sinusitis that has been treated with a variety of oral antibiotics. His last episode of sinusitis, which occurred about 1 month ago, was treated with a 10-day course of cephalexin. He denies any nausea or vomiting and has not experienced any seizures in the recent past. L.Y. was tested for HIV 6 months ago, and the result of his antibody test was negative. He takes no current medications, denies smoking and use of recreational drugs,

and drinks alcohol only on social occasions a few times a month. L.Y. has no known drug allergies.

Physical examination reveals L.Y. to be in mild distress, with a temperature of 100.76 °F (38.2 °C). He is slightly lethargic and is oriented to person and place but not time. The strength in L.Y.'s left arm is 3/5; the strength in his left leg is 4/5. The remainder of his neurologic examination is grossly normal. L.Y. described moderate pain on palpation of his frontal sinuses, and a purulent discharge is noted.

Laboratory evaluation shows the following:

WBC count, 8000 cells/μL, with 70% PMN, 25% lymphocytes, and 5% monocytes
BUN, 16 mg/dL
SCr, 1.2 mg/dL
Erythrocyte sedimentation rate (ESR), 40 mm/hour
Hgb, Hct, platelets, and serum chemistries are within normal limits.

A CT scan with contrast dye reveals a right frontal ring-enhancing lesion with a small amount of surrounding cerebral edema. L.Y. is admitted to the neurosurgery unit for further evaluation and treatment.

What clinical signs and symptoms that are suggestive of bacterial brain abscess does L.Y. display? How can brain abscess be diagnosed in L.Y.?

L.Y. has presented to the ED with many signs and symptoms suggestive of bacterial brain abscess. He is 40 years old and male, both of which place him in a group with the highest likelihood of having a brain abscess. In contrast to the diffuse nature of meningitis, brain abscess presents as a focal neurologic process. Notable in L.Y.'s presentation is left-sided (arm and leg) weakness. Symptoms of brain abscess range in severity from indolent to fulminant, and in most patients, the duration of symptoms at the time of presentation is ≤2 weeks.[113] Headache is the most common symptom of brain abscess, occurring in ~70% of cases. L.Y.'s clinical manifestations have become gradually worse over the past week, and his worsening headaches, increasing drowsiness, and difficulty in concentrating all are consistent with bacterial brain abscess.

L.Y. presents with the classic triad of fever, headache, and focal neurologic deficits. Although this triad should always be looked for, fewer than half of patients with confirmed bacterial brain abscess present in this manner.[112]

The absence of fever does not rule out infection because fever is found in <50% of patients.[110],[113] Focal neurologic deficits are present in ~50% of patients and vary in nature and severity in relation to the location and size of the abscess and surrounding cerebral edema. Although L.Y. does not have a history of seizure activity, ~25% of patients experience partial seizures that often become generalized. Papilledema and nuchal rigidity occur in ≤25% of cases and often are not useful in confirming the diagnosis. Symptoms associated with a contiguous focus of infection should always be sought, and in some situations, they may dominate the clinical picture.[112] L.Y. has a history of sinus infection, and the pain on palpation of his sinuses coupled with the purulent sinus drainage suggests active infection at this site.

As can be seen from L.Y.'s test results, laboratory evaluation usually is not very helpful when diagnosing brain abscess. L.Y. does not have a peripheral leukocytosis, but he does have an elevated ESR. A normal peripheral WBC count is not unusual in patients with intracranial suppuration. The ESR often is elevated in brain abscess, but this test is nonspecific and only indirectly supports the diagnosis.

L.Y. did not have a lumbar puncture because this procedure is contraindicated for diagnosing brain abscess. The diagnostic yield from CSF is low because chemistries (eg, protein, glucose, WBC) usually are normal and culture of the CSF in patients with brain abscess is unlikely to yield the causative pathogen. More important, performing a lumbar puncture in patients with space-occupying lesions of the brain can produce cerebral herniation as a consequence of the shifting pressure gradient induced within the cranial vault after insertion of the lumbar puncture needle.[118]

Of paramount importance is the abnormality detected on the CT scan of L.Y.'s brain. When dye is injected before the CT scan, brain abscesses will appear to "ring enhance." Furthermore, cerebral edema can be identified as a variable hypodense region immediately surrounding the abscess cavity. As stated earlier, CT and MRI scanning techniques have revolutionized the diagnosis and treatment of brain abscess.[112],[119] In general, a good correlation exists

between the clinical and radiologic response to therapy of bacterial brain abscess.

TREATMENT

CASE 65-5, QUESTION 2: How should L.Y.'s brain abscess be treated?

SURGICAL TECHNIQUES

A combined medical and surgical approach is the best form of therapy for L.Y.'s brain abscess. Response rates to antimicrobial therapy alone have been disappointing, and with a few exceptions, surgical intervention is necessary to ensure optimal results. Modern stereotactic neurosurgical techniques allow almost any brain abscess that is ≥1 v in diameter to be drained via stereotactic aspiration, regardless of location. Primary medical therapy may be indicated if imaging does not show a central cavity in the abscess or if surgery is withheld for other reasons such as poor health status.[113]

The two types of surgical approaches for brain abscess are (a) stereotactic navigation with needle aspiration and (b) intraoperative ultrasonography through a burr hole or craniotomy for direct abscess drainage.[113] Stereotactic aspiration of abscess is highly effective and is associated with lower morbidity and mortality than is craniotomy.[120] Modern medical advances leave total resection with a very limited role unless an abscess is superficial or when there is high suspicion of fungal or tuberculous infection.[113]

ANTIMICROBIAL PENETRATION INTO BRAIN ABSCESS

Antimicrobial therapy is an essential component of brain abscess therapy. Penetration of antibiotics into brain abscess fluid has not been studied as carefully as penetration into CSF, and as discussed earlier, the barrier involved is different (see Fig. 65-1).[8] Penicillins and cephalosporins penetrate adequately into abscess fluid, but certain agents (eg, penicillin G) may be susceptible to degradation

by enzymes present within the abscess milieu.[110] Third-generation cephalosporins (eg, cefotaxime, ceftriaxone) penetrate sufficiently into the abscess and thus are appropriate choices when gram-negative bacteria are present.[110],[121] Metronidazole achieves abscess fluid concentrations equal to or in excess of serum levels and is bactericidal against strict anaerobes. The unique mechanism of action of metronidazole makes it particularly useful in the necrotic core of the cavity, where the oxidation-reduction potential is low and bacteria replicate slowly or are dormant. For these reasons, metronidazole is the drug of choice for anaerobic gram-negative bacterial brain abscess.[110] Vancomycin and carbapenems also penetrate sufficiently into brain abscess fluid.[110],[122] Although specific abscess-penetration data are unavailable, successful treatment of cerebral nocardiosis with TMP-SMX and CNS toxoplasmosis with clindamycin suggests that these compounds also achieve adequate penetration into cerebral abscess cavities.[123],[124]

ANTIBIOTIC THERAPY

When antibiotic therapy should be instituted depends on the status of the patient and the stage of abscess development. For patients diagnosed during the cerebritis stage, before formation of a well-circumscribed capsule, surgery should be delayed and antimicrobial therapy begun in patients with significant symptoms.[110],[121] If capsule formation already has taken place and if the patient's clinical status allows, it is reasonable to delay initiation of antibiotics until after surgery if surgery is to be performed within hours to increase the microbiologic yield from tissue and fluid samples. If the disease is fulminant, antibiotics must be instituted promptly and surgical intervention performed as quickly as possible.[113]

L.Y.'s clinical presentation suggests an advanced brain abscess. The presence of ring enhancement on CT and the onset of symptoms over 2 weeks support this conclusion. Because he is not critically ill, antibiotic therapy may be delayed until surgery is performed. Specimens obtained from the surgical procedure should

be sent for aerobic and anaerobic culture and an immediate Gram stain.

Initial antibiotic therapy for brain abscess needs to be sufficiently broad to cover the most likely pathogens (Table 65-9). When the implicated source is contiguous such as oral, otogenic, or sinus, metronidazole plus ceftriaxone (with the addition of vancomycin with a sinus source) is recommended.[110,113] Metronidazole will provide coverage for strict anaerobes, including *Bacteroides* and *Prevotella* species. When the implicated source is head trauma with skull fracture or is associated with a neurosurgical procedure, empiric therapy should consist of vancomycin, metronidazole, and a third- or fourth-generation cephalosporin. For hematogenous sources, a third-generation cephalosporin, metronidazole, and vancomycin are recommended.[113] Vancomycin is added to cover staphylococcal infection.

For L.Y., therapy with ceftriaxone 2 g IV every 12 hours, vancomycin 1 g IV every 8 hours, and metronidazole 500 mg IV every 8 hours should be started postoperatively (see Table 65-6).

ADJUNCTIVE CORTICOSTEROID THERAPY

Adjunctive corticosteroid therapy for bacterial brain abscess is controversial. Steroids can interfere with antibiotic penetration into abscesses and obscure the interpretation of serial CT scans when assessing response to therapy. Therefore, steroids are indicated only if significant cerebral edema is present, particularly if it is accompanied by rapid neurologic deterioration.[110,121] L.Y. should not receive dexamethasone because his mental status is only mildly depressed and the cerebral edema seen on CT scan is not massive.

ADJUNCTIVE ANTICONVULSANT THERAPY

L.Y. has shown no sign of seizure activity thus far and, therefore, does not require anticonvulsant therapy. However, anticonvulsants should be used in the acute setting when seizures are present.[110,121] Agents with activity against partial and complex partial seizures are preferred (eg, phenytoin, carbamazepine, and, potentially,

levetiracetam). The long-term use of anticonvulsants depends on whether seizure activity persists. Insufficient information exists regarding how long to continue anticonvulsants in such cases. Therefore, discontinuation of these agents must be individualized.

No formal guidelines are available regarding the optimal duration of therapy for bacterial brain abscess. Given the serious nature of the infection and the difficulty associated with antibiotic penetration, high-dose IV therapy should continue for at least 6 to 8 weeks.[110,113] The duration of therapy should be evaluated on a case-by-case basis. In an attempt to ensure complete eradication of infection, some experts recommend long-term (2–6 months) oral antibiotics after the IV course, provided agents with good oral absorption and activity against the offending pathogens are available.[110]

MONITORING THERAPY

Case 65-5, Question 3: How should L.Y. be monitored for therapeutic response and toxicity?

Although L.Y. is on antibiotic therapy, weekly or biweekly CT scans should be obtained to evaluate abscess resolution. His clinical response to therapy also should be assessed daily. If therapy is effective, L.Y.'s mental status should improve gradually (eg, he will become more alert and oriented) over a period of several days. L.Y.'s headaches and hemiparesis (weakness in his arm and leg) also should resolve eventually. It may take a week or longer, however, to see a complete resolution of symptoms.[110] In general, radiologic improvement (ie, reduction in abscess size) correlates reasonably well with clinical response, but not always. Persistent symptoms or failure to detect a reduction in abscess size on CT scan or the appearance of new abscesses may indicate improper antimicrobial therapy or the need for more surgery.[110,121] Repeated surgical intervention with appropriate reculturing may be required in some instances to optimize therapy.

Adverse effects associated with the penicillin G therapy that L.Y. is receiving are similar to those of other β-lactam antibiotics. Seizures are a potential complication when high doses of penicillin are used in the presence of a mass lesion in the brain.[125] L.Y. should be observed closely by those providing care and questioned regularly for any evidence of seizure activity. Metronidazole usually is well tolerated, but may cause neurotoxicity, most commonly peripheral neuropathy. L.Y. should be assessed for the presence of numbness or tingling in his hands or feet. Seizures, although uncommon, occasionally occur with metronidazole. If L.Y. experiences peripheral neuropathy or seizures, a switch to meropenem would be appropriate. Other adverse effects associated with metronidazole include mild nausea, brownish discoloration of the urine, peripheral neuropathies, and the potential for a disulfiram-like reaction with concomitant ethanol ingestion.[126] L.Y. should be counseled regarding the possibility of gastric upset and discoloration of the urine, and he should be strongly cautioned to avoid alcoholic beverages while receiving metronidazole. Given his young age, the absence of significant underlying diseases, and the relative early detection of his brain abscess, there is every reason to expect a good response to his treatment and, eventually, a complete resolution of his abscess.

Endocarditis

Annie Wong-Beringer, Rachid Douglas-Louis, and Emi Minejima

CORE PRINCIPLES		CHAPTER CASES
1	Infective endocarditis (IE) is a microbial infection of the heart valves or other endocardial tissue, usually associated with an underlying cardiac defect. Between 2000 and 2011, IE incidence has increased, accounting for ~29,000 to 47,000 cases per year. *Streptococcus viridans*, *Staphylococcus aureus*, and *Enterococcus* species are common causes of IE. Other rare pathogens affecting special populations include *S. epidermidis*, *Pseudomonas aeruginosa*, and *Candida* species.	**Case 66-1 (Question 1) Case 66-2 (Question 1) Case 66-3 (Question 1) Case 66-4 (Question 1) Case 66-5 (Questions 1, 4, 6)**
2	Clinical presentation may be highly variable and characterized by nonspecific symptoms such as fever, weight loss, fatigue, night sweats, and	**Case 66-1 (Question 1) Case 66-2 (Question 2), Figures 66-1–66-3**

	arthralgias. Peripheral manifestations specific to IE include conjunctival petechiae, Janeway lesions, and splinter hemorrhages. Major embolic episodes and infarction involving other organs can develop in up to one-third of cases. Congestive heart failure (CHF) is the most common cause of death in IE and the most common indication for surgery.	
3	The American Heart Association (AHA) recommends use of the modified Duke criteria as the primary diagnostic schema to evaluate patients suspected of having IE. The most important factor confirming IE is positive blood culture findings. Transesophageal echocardiogram (TEE) is a valuable tool to strengthen diagnosis and identify patients at risk for complications and need for surgical interventions.	**Case 66-1 (Question 2), Tables 66-1, 66-2**
4	General treatment approach to organism eradication requires the administration of parenteral bactericidal antibiotics at high doses for a prolonged duration of 4 to 6 weeks. Combination therapy is common to achieve synergy for some pathogens. Selection of regimen should be based on organism sensitivity, tissue penetration, and host tolerance of the antibiotic agent(s). The AHA treatment guideline by organisms should be followed.	**Case 66-1 (Questions 3–5) Case 66-2 (Question 3) Case 66-3 (Questions 2–4) Case 66-4 (Questions 1–5) Case 66-5 (Questions 2, 3, 5, 7), Tables 66-3–66-5**

5	Treatment of IE caused by methicillin-resistant *Staphylococcus aureus* (MRSA) and by enterococci presents significant challenges owing to the emergence of resistance to standard therapy, vancomycin. Higher doses of vancomycin targeting an area under the 24-hour plasma concentration–time curve to the minimum inhibitory concentration (AUC_{24hr}/MIC) ≥400 mg*hour/L are advocated for treatment of MRSA IE but may be associated with increased incidence of nephrotoxicity. Alternative agents for the treatment of IE caused by vancomycin-resistant enterococci have limited clinical success or lack of clinical evidence.	**Case 66-3 (Questions 3, 4) Case 66-4 (Question 5)**
6	Fungal endocarditis is rare but carries poor prognosis. It occurs primarily in intravenous drug users (IVDUs), patients with prosthetic heart valves or intravenous (IV) catheters, and those with a compromised immune system. Management generally requires early valve replacement and combination antifungal therapy.	**Case 66-5 (Questions 1–3)**
7	The AHA recommends the use of antibiotic prophylaxis in select patients with specific cardiac conditions associated with the highest risk of adverse outcomes from endocarditis, who are undergoing dental or respiratory procedures known to cause	**Case 66-6 (Questions 1, 2), Tables 66-6, 66-7**

significant bacteremia. Antimicrobial prophylaxis should be directed against viridans group streptococci.

INTRODUCTION

Infective endocarditis (IE) is a microbial infection of the heart valves or other endocardial tissue, often associated with an underlying cardiac defect. IE is classified based on the causative organism to provide information on the probable microbial cause and course of the disease (acute or subacute), the likelihood of underlying heart disease, and the appropriate antimicrobial regimens.[1]

Pathogenesis

The pathogenesis of endocarditis involves a complex series of events that ultimately result in the formation of an infected platelet-β-fibrin thrombus on the valve surface.[1,2] This thrombus is called a *vegetation.*

The first step in the formation of the vegetation involves modification of the endocardial surface, which is normally nonthrombogenic. Valvular insufficiency, for example, caused by aortic stenosis or ventricular septal defects, can produce regurgitant blood flow, high-pressure gradients, or narrow orifices, resulting in turbulence and endocardial damage.[1,2] In patients with rheumatic heart disease, endocardial injury (eg, mitral valve stenosis) occurs as a result of immune complex deposition or hemodynamic disturbances. Once the endocardial surface of the valve is traumatized, small, sterile thrombi consisting of platelets and fibrin are deposited, forming the lesion called nonbacterial thrombotic endocarditis (NBTE).[1,2] NBTE occurs most commonly on the atrial surfaces of the mitral and tricuspid valves and on the ventricular surface of the aortic valve. NBTE serves as a nidus for microbial

colonization during periods of bacteremia (eg, procedures involving perforation of the oral mucosa, respiratory tract, genitourinary tract, or infected skin). Organisms such as viridans group streptococci (VGS), *Enterococcus* spp., *Staphylococcus aureus*, *S. epidermidis*, *Pseudomonas aeruginosa*, and *Candida albicans* possess adherence factors that facilitate their pathogenicity. In particular, platelet aggregation is an important virulence factor in experimental streptococcal endocarditis, potentially leading to larger vegetations and multifocal embolic spread.[3]

Once the NBTE lesion becomes colonized by microorganisms, the surface is rapidly covered with a sheath of fibrin and platelets. This avascular encasement provides an environment protected from host defenses and is conducive to further bacterial replication and vegetation growth.[2] The bacterial colony count can be as high as 10^4 to 10^5 bacteria per gram of valvular vegetation. Endocarditis can result in life-threatening hemodynamic disturbances and embolic episodes affecting many organs. Without antimicrobial therapy and surgical intervention, IE is virtually 100% fatal. Because of bacterial proliferation to high densities in the fibrin mesh protected from normal host defenses, cure of infection requires prolonged therapy of 4 to 6 weeks with relapse not uncommon.

Epidemiology

Between 2000 and 2011, there were >450,000 IE-related hospitalizations in the United States alone. Over that decade, the incidence has increased from 11 to 15 cases per 100,000 persons, with an associated mortality of 11% to 26%.[4–6] Health care–associated IE has emerged as a result of increased use of invasive medical devices and procedures (eg, intravenous [IV] catheters, total parenteral nutrition [TPN] IV lines, hemodialysis shunts or fistulas, intracardiac prosthesis, and central venous pressure monitoring lines).[1] With the exception of intravenous drug users (IVDUs), the mean patient age has shifted from younger than 30 years in the 1920s to older than 55 years at the turn of the century.[7–9] This

increase in age is likely attributable to (a) a decline in the incidence of acute rheumatic fever and rheumatic heart disease, counterbalanced by degenerative valvular disease in an increasing elderly population, (b) the increasing longevity of the general population, and (c) increased exposure to more intense and invasive medical procedures in both, the overall and the aging population. Males are infected more often than are females (roughly 2:1), and the disease remains uncommon in children, occurring primarily in association with underlying congenital cardiac defect and nosocomial catheter-related bacteremia.[1]

Predisposing Factors

In general, any structural cardiac defect that leads to the turbulence of blood flow predisposes to the development of IE. Rheumatic heart disease was at one time the most common underlying cardiac defect associated with endocarditis; however, cases related to rheumatic heart disease have declined to ≤25% in developed countries while remaining the predominant defect in developing countries.[7,8] Mitral valve prolapse with thickened leaflets and valvular redundancy is a recognized predisposing risk for IE, with a documented occurrence rate of 10%. Clinical presentation is often subtle, with lower associated mortality in these individuals compared with left-sided IE of other types. In the absence of underlying valvular defects, degenerative cardiac lesions, such as calcified mitral annulus secondary to atherosclerotic cardiovascular disease and post-myocardial infarction thrombus, may be a significant risk factor for the elderly. IVDUs constitute a unique population at greatest risk for recurrent and polymicrobial IE.[7] Hemodialysis dependency (8%), diabetes mellitus (16%), and congenital heart disease (12%) are the most common demographic characteristics associated with IE.[10] Up to 25% of all cases are acquired in health care–related settings, whereas community acquisition accounts for the majority of the cases. Between 2000 and 2014, there have been an increased proportion of community-associated IE cases due to IVDU,

accounting for 12% to >50% in certain regions in the United States.[11–13]

Bacteriology

Streptococci and staphylococci cause 80% to 90% of cases of IE. VGS remain the predominant cause of IE in children and in young females with isolated mitral valve involvement.[1] During the past decades, staphylococci have become increasingly prevalent as a cause of IE, and *S. aureus* is the leading cause of IE.[10] Acquisition of IE in nearly half of these cases was likely health care related, supporting a low threshold to evaluate underlying IE in the setting of health care–related *S. aureus* bacteremia. More importantly, methicillin-resistant strains account for up to 40% of IE cases involving *S. aureus*.[7–9] Endocarditis in IVDUs often is caused by *S. aureus*, whereas prosthetic valve endocarditis (PVE) is more commonly caused by coagulase-negative staphylococci, such as *S. epidermidis*. Gram-negative bacilli and fungi together account for <10% of all endocarditis cases and usually are associated with IV drug use, valvular prostheses, and hospital IV access procedures. Endocarditis caused by anaerobes and other organisms is rare. Polymicrobial IE (caused by at least two organisms), although uncommon, is being recognized more frequently in IVDUs and certain postoperative patients. *Candida* species, *S. aureus*, *P. aeruginosa*, *Serratia marcescens*, and non-β hemolytic group D streptococci are the organisms involved most frequently in these populations.

Site of Involvement

The site of heart valve involvement is determined by the underlying cardiac defect and the infecting organism.[2,7,9,10] The mitral valve is affected in >85% of cases caused by VGS with underlying rheumatic heart disease. The tricuspid valve is the common site of involvement in staphylococcal endocarditis associated with IVDU. Overall, the

distribution ranges from 28% to 45% for mitral valve, 5% to 36% for aortic valves, and 0% to 6% for tricuspid valves, and the pulmonary valve is rarely affected.[14] Multiple heart valves may be affected simultaneously.

CASE 66-1

QUESTION 1: A.G., a 57-year-old, 132.28-pound (60-kg) male with fatigue, a persistent low-grade fever, night sweats, arthralgias, and a 15.43-pound (7-kg) unintentional weight loss, is admitted to the hospital for evaluation. Visual inspection reveals a cachectic, ill-appearing male in no acute distress. Physical examination is significant for a grade III/IV diastolic murmur with mitral regurgitation (insufficiency), increased from preexisting murmur, a temperature of 100.50 °F (38.05 °C), petechial skin lesions, subungual splinter hemorrhages, and Janeway lesions on the soles of both feet (**Figs. 66-1, 66-2, and 66-3**). Nail clubbing, Roth spots, or Osler nodes are not evident. The remainder of his physical examination is unremarkable. A.G.'s medical history is significant for mitral valve prolapse and, more recently, a dental procedure involving the extraction of four wisdom teeth. The history of his present illness is noteworthy for the development of symptoms 2 weeks after the dental procedure (about 2 months before admission). His only current medication is ibuprofen 600 mg orally four times a day.

Figure 66-1 Janeway lesions. Extensive ecchymotic embolic lesions in a case of acute bacterial endocarditis.

Figure 66-2 Splinter hemorrhages in the nail bed.

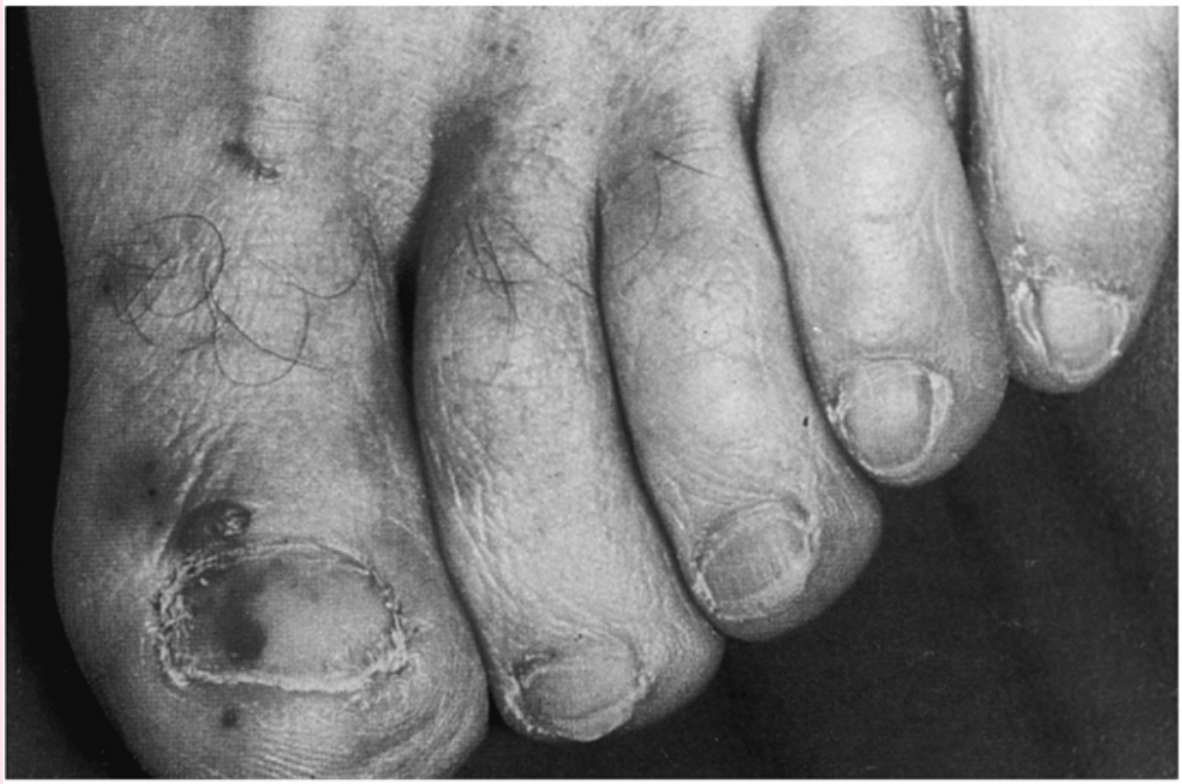

Figure 66-3 Petechial skin lesions in a case of acute staphylococcal endocarditis.

Relevant laboratory results include the following:

Hemoglobin (Hgb), 11.4 g/dL (SI units, 114 g/L [normal, 140–180])
Hematocrit (Hct), 34% (SI units, 0.34 [normal, 0.39–0.49])
Reticulocyte count, 0.5% (SI units, 0.005 [normal, 0.001–0.024])
White blood cell (WBC) count, 35,000/μL with 65% polys and 1% bands (SI units, 35 × 10/L with 0.65 polys and 0.01 bands [normal, 3.2–9.8 with 0.54–0.62 polys and 0.03–0.05 bands])
Blood urea nitrogen (BUN), 21 mg/dL (SI units, 7.5 mmol/L of urea [normal, 2.9–8.9])
Serum creatinine (SCr), 1.2 mg/dL (SI units, 159 mmol/L [normal, 53–133])

A urinalysis (UA) reveals 2+ proteinuria and 10 to 20 red blood cells (RBCs) per high-power field (HPF). The erythrocyte sedimentation rate (ESR) is elevated at 66 mm/hour (normal, ≤30 mm/minute), and the rheumatoid factor (RF) finding is positive. Results from a transthoracic echocardiogram (TTE) were unrevealing. Three blood cultures were obtained over 24 hours, and all cultures obtained on day 1 are growing gram-positive cocci in pairs and chains, presumed α-hemolytic streptococci. Although confirmation and speciation of the organism is being performed, A.G. is started empirically on penicillin G, 2 million units IV every 4 hours (12 million units per day), and IV gentamicin, 120 mg

(loading dose) followed by 60 mg every 8 hours. Antimicrobial susceptibility results are pending.

What clinical manifestations and laboratory abnormalities in A.G. are consistent with IE?

VIRIDANS GROUP *STREPTOCOCCUS* ENDOCARDITIS

Clinical Presentation

The clinical presentation of IE is highly variable and can involve almost any organ system.[1] A.G. appears pale and chronically ill and represents the typical patient with subacute disease (eg, that caused by VGS). Nonspecific symptoms consistent with endocarditis in A.G. include fatigue, weight loss, fever, night sweats, and arthralgias. Fever alone is present in most (90%) patients with endocarditis. The fever is characteristically low grade and remittent, with peaks in the afternoon and evening. Fever may be absent or minimal in patients with CHF, chronic renal and liver failure, prior use of antimicrobial agents, or IE caused by less virulent organisms.[1] Musculoskeletal symptoms (eg, arthralgias, myalgias, and back pain) are common and may mimic rheumatic disease. Other symptoms can include lethargy, anorexia, malaise, nausea, and vomiting.[1] Because signs and symptoms are nonspecific and subtle, diagnosis is often difficult to make. In addition, the time from bacteremia to diagnosis is often prolonged because of the insidious progression of symptoms.[1] Delayed diagnosis occurs more commonly in the elderly. Fever may be absent in 30% to 40% of patients older than age 60 years, whereas it can be present in >90% of patients younger than age 40 years.

Elderly patients are less likely to have new or changed heart murmurs. The most common presenting symptoms in the elderly with endocarditis are confusion, anorexia, fatigue, and weakness, which may be readily attributable to stroke, heart failure, or syncope.

The temporal relationship between A.G.'s dental procedure and the onset of symptoms suggests it was the etiology of bacteremia and subsequent endocarditis. Although one assumes that prophylactic antibiotics were administered before the procedure, endocarditis can develop despite receipt of adequate chemoprophylaxis.[1,10,14] A.G. has an increase in his preexisting diastolic murmur with mitral insufficiency, a finding consistent with endocarditis. Cardiac murmurs are present in >85% of patients with endocarditis. Murmurs frequently are absent in patients with acute disease (eg, staphylococcal endocarditis), right-sided disease (eg, endocarditis in IVDUs), or mural infection.[1]

A.G. exhibits several peripheral manifestations of IE, including conjunctival petechiae, Janeway lesions, and splinter hemorrhages. Overall, peripheral manifestations are observed in 10% to 50% of cases, but none of these is pathognomonic for IE.[1] These manifestations are usually a result of septic embolization of vegetations to distal sites or immune complex deposition. Mucocutaneous petechial lesions of the conjunctiva, mouth, or pharynx are present in 20% to 40% of patients, especially those with long-standing disease.[1] These lesions generally are small, nontender, and hemorrhagic in appearance, and result from vasculitis or peripheral embolization. Janeway lesions are painless, hemorrhagic, macular plaques most commonly found on the palms and soles (Fig. 66-1). Splinter hemorrhages are nonspecific findings that appear as red to brown linear streaks in the proximal portion of the fingers or toenails (Fig. 66-2). Other findings can include Roth spots (small, flame-shaped retinal hemorrhages with pale white centers found near the optic nerve) and Osler nodes (purplish, nonhemorrhagic, painful nodules that develop on the subcutaneous pads of the fingers and toes or on the palms and soles). Clubbing (broadening and thickening) of the nails also may be observed in patients with prolonged disease. Petechial skin lesions are also seen (Fig. 66-3).

Several laboratory findings are consistent with IE in A.G. A low Hgb and Hct with normal red cell indices suggest anemia of chronic disease. Of patients with subacute disease, 70% to 90% will have a

normochromic, normocytic anemia. Leukocytosis with a left shift, although not evident in A.G., commonly is seen in those with acute, fulminant disease such as staphylococcal endocarditis. The ESR nearly always is elevated in IE, but this finding is nonspecific and can be associated with several other disease entities. RF (an immunoglobulin M antiglobulin) and circulating immune complexes are detected in most patients with long-standing disease, but both are nonspecific findings.[1] Major embolic episodes and infarction involving the kidney, spleen, lung, and brain may develop as secondary complications in up to one-third of cases.[1] A.G. exhibits some degree of renal damage, as evidenced by moderate hematuria and proteinuria. Alterations in A.G.'s renal function (increased BUN and creatinine) probably are a result of immune complex deposition (diffuse glomerulonephritis) or secondary to renal embolization (focal glomerulonephritis). Erythrocyte and leukocyte cast formation also may be present. Renal impairment usually is reversible with the institution of effective antimicrobial therapy.[1,15] Cardiac complications occur most frequently. CHF from infection-induced valvular damage is the most common cause of death in IE and is the most common indication for surgery.[1,15] As many as two-thirds of patients with endocarditis develop CHF. Aortic valve infection is more frequently associated with CHF than is mitral valve infection. Other manifestations include paravalvular abscesses, pulmonary edema, and pericarditis.[15] Mitral valve injury caused by VGS generally is better tolerated hemodynamically than is aortic valve injury caused by staphylococci. Although A.G. has no apparent signs of overt heart failure, he should be monitored closely for the development of hemodynamic instability. Neurologic complications, most commonly stroke, rank second to cardiac complications in frequency, but they may be the leading cause of death in patients with endocarditis.[15] A stroke syndrome in a patient with underlying valvular abnormalities should prompt the clinician to rule out IE. Other clinical manifestations include headache, mental status change, transient ischemic attack, seizures, brain abscess, or intracranial mycotic aneurysms.[1,15] Neurologic symptoms associated with high mortality can be observed in up to 35% of patients with *S. aureus* endocarditis

who are non-IVDUs.[16] Metastatic abscesses (eg, in the spleen, kidney, liver, and iliac and mesenteric arteries) can develop in virtually any organ secondary to systemic septic embolization[15] Splenomegaly, although not part of A.G.'s findings, occurs in 20% to 60% of all cases and is more common in subacute disease.

Diagnosis

Case 66-1, Question 2: How was the diagnosis of IE established in A.G.?

BLOOD CULTURES

Although A.G.'s medical history (mitral valve prolapse, recent dental procedure) and clinical presentation are highly suggestive of IE, blood culture is the single most important diagnostic workup for IE.[1] Bacteremia (when present) secondary to endocarditis is continuous and low grade; >50% of the cultures show only 1 to 30 bacteria per milliliter. Despite the low concentration of organisms, at least one of the first two blood culture results is positive in 95% of cases.[1] To achieve a high yield, at least three sets of blood cultures collected by separate venipunctures should be obtained, with the first and third set of blood cultures taken at least 1 hour apart.[1] Administration of antibiotics within the previous 2 weeks may significantly decrease this yield.[17] It is also important to establish the exact microbiologic cause before initiating antimicrobial therapy. In patients who are acutely ill, empiric therapy should start as soon as the appropriate cultures are obtained to avoid further valvular damage or other complications.[1]

ECHOCARDIOGRAPHY

Echocardiography is a valuable tool in establishing early diagnosis (eg, the presence and size of vegetations), identifying patients at high risk for complications, and optimizing the timing and mode of surgical intervention by detecting and monitoring associated pathologic changes such as valvular abscess.[1],[18],[19] The transducer

may be placed on the chest (TTE) or in the esophagus (transesophageal echocardiogram [TEE]).[19] TTE is a rapid and noninvasive procedure with 98% specificity for vegetations. Sensitivity for vegetations may be <60% to 70%, however, for adult patients with obesity, hyperinflated lungs caused by emphysema, or a prosthetic valve. TEE is more costly and invasive but is significantly more sensitive in detecting vegetations and abscesses while maintaining high specificity. All patients with suspected IE should have echocardiography on admission and repeated during their course, to help guide future medical management and timing of intervention.[19] Compared with TTE, TEE is superior in the diagnosis of pacemaker IE and IE in the elderly. A.G. has a negative TTE result on admission. Given the high clinical suspicion for IE in A.G., a follow-up TEE is recommended to rule out a false-negative TTE result.

Diagnostic criteria for IE that integrate clinical, laboratory, microbiologic, and echocardiographic data are listed in **Tables 66-1** and **66-2**.[10],[20] Based on published evidence involving nearly 2000 patients, the 2015 AHA guidelines suggest that the modified Duke criteria be used as the primary diagnostic schema to evaluate patients suspected of having IE.[10] A.G. possesses one major criterion (positive blood cultures) and three minor criteria (fever, predisposing heart condition, and vascular and immunologic phenomena); therefore, he meets the diagnostic criteria for definite IE.[20]

Table 66-1

Definition of Infective Endocarditis According to the Modified Duke Criteria

Definite IE[a]
Pathologic Criteria
Microorganisms: demonstrated by culture or histology examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; *or*
Pathologic lesions: vegetation or intracardiac abscess confirmed by histologic

examination showing active endocarditis
Clinical Criteria
Using specific definitions listed in Table 66-2; two major criteria *or* one major and three minor criteria *or* five minor criteria
Possible IE
One major criterion and one minor criterion; *or* three minor criteria
Rejected
Firm alternative diagnosis explaining evidence of IE; *or*
Resolution of IE syndrome with antibiotic therapy for >4 days; *or*
No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for >4 days; *or* not meet criteria for possible IE as above

IE, infective endocarditis.

[a]Modifications shown in bold.

Table 66-2
Definitions of Terminology Used in the Modified Duke Criteria for the Diagnosis of Infective Endocarditis

Major Criteria[a]
Blood Culture Positive for IE
▪ Typical microorganisms consistent with IE from two separate blood cultures: **1.** Viridans streptococci, *Streptococcus bovis*, HACEK group; *or* **2.** *Staphylococcus aureus* or community-acquired enterococci in the absence of a primary focus; *or* ▪ Microorganisms consistent with IE from persistently positive blood cultures defined as follows: **1.** At least two positive blood cultures drawn >12 hours apart; *or* **2.** All of three or a majority of four separate blood cultures (with first and last sample drawn at least 1 hour apart) ▪ **Single positive blood culture for *Coxiella burnetii* or antiphase 1 IgG antibody titer >1:800**
Evidence of Endocardial Involvement

- Echocardiogram positive for IE **(TEE recommended for patients with prosthetic valves, rated at least "possible IE" by clinical criteria or complicated IE [paravalvular abscess]; TEE as first test in other patients)** defined as follows:
  1. Oscillating intracardiac Masson valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; *or*
  2. Abscess; *or*
  3. New partial dehiscence of prosthetic valve
- New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

Minor Criteria

- Predisposition: predisposing heart condition or IV drug use
- Fever >100.40 °F (38 °C)
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, RF
- Microbiologic evidence: positive blood culture but not meeting major criterion as noted earlier[b] or serologic evidence of active infection with organism consistent with IE
- **Echocardiographic minor criteria eliminated**

HACEK, *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, and *Kingella kingae*; IE, infective endocarditis; IgG, immunoglobulin G; IV, intravenous; RF, rheumatoid factor; TEE, transesophageal echocardiography.

[a]Modifications shown in bold.

[b]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

From Li JS, Sexton DJ, Nettles R, et al. Proposed modifications to the Duke criteria for the diagnosis of infective endocarditis. *Clin Infect Dis*. 2000;30(4):633–638. Reproduced by permission of Infectious Diseases Society of America.

Antimicrobial Therapy

GENERAL PRINCIPLES

Case 66-1, Question 3: What would be a reasonable duration of antibiotic therapy for A.G.?

The avascular nature of the vegetation results in an environment that is devoid of normal host defenses (eg, phagocytic cells and complement); this permits uninhibited growth of bacteria.[2] Therefore, to eradicate the causative organism, high doses of an IV bactericidal antibiotic generally are administered for 4 to 6 weeks.[1,10]

Table 66-3
Suggested Regimens for Therapy of Native Valve Endocarditis Caused by *Streptococcus viridans* Group and *Streptococcus gallolyticus*

Antibiotic	Dose[a,b] and Route	Duration
Penicillin-Susceptible (minimum inhibitory concentration [MIC] ≤0.12 µg/mL)		
Aqueous crystalline penicillin G[c] *or*	*Adult*: 12–18 million units/24 hour IV either continuously or in four to six equally divided doses	4 weeks
	Pediatric: 200,000 units/kg/24 hour IV (max: 20 million units/24 hour) either continuously or in four to six equally divided doses	
Ceftriaxone sodium[c]	*Adult*: 2 g once daily IV or IM	4 weeks
	Pediatric: 100 mg/kg once daily IV or IM	
Or		
Aqueous crystalline penicillin G *or*	See penicillin-susceptible dosing for penicillin given earlier	2 weeks
Ceftriaxone sodium	See penicillin-susceptible dosing for ceftriaxone given earlier	2 weeks
With gentamicin sulfate[d]	*Adult*: 3 mg/kg once daily IV or IM	2 weeks
	Pediatric: 3 mg/kg once daily IV or IM or in three equally divided doses	
Relatively Penicillin G Resistant (MIC >0.12 and <0.5 µg/mL)		
Aqueous crystalline penicillin G	*Adult*: 24 million units/24 hour IV either continuously or in four to six equally divided doses	4 weeks

	Pediatric: 200,000–300,000 units/kg/24 hour IV (max: 20 million units/24 hour) either continuously or in four to six equally divided doses	
With gentamicin sulfate[d]	*Adult*: 3 mg/kg once daily IV or IM *Pediatric*: 3 mg/kg once daily IV or IM or in three equally divided doses	2 weeks
Or		
Ceftriaxone sodium[c]	*Adult*: 2 g once daily IV or IM *Pediatric*: 100 mg/kg once daily IV or IM	4 weeks
β-*Lactam Allergic*		
Vancomycin hydrochloride[e]	*Adult*: 15–20 mg/kg every 8–12 hours (adjust dose based on AUC-guided monitoring)	4 weeks
	Pediatric (3 months to <12 years): 60–80 mg/kg/24 hour IV in four equally divided doses (max: 3 g/24 hour; adjust dose based on AUC-guided monitoring) *Pediatric (≥12 years):* 60–70 mg/kg/24 hour IV in three to four equally divided doses (max: 3 g/24 hour; adjust dose based on AUC-guided monitoring)	

AUC, area under the curve; IM, intramuscular; IV, intravenous.

[a]Pediatric doses should not exceed that of a normal adult.

[b]Antibiotic doses for patients with impaired renal function should be modified appropriately.

[c]Preferred in most patients older than 65 years of age and in those with impairment of the eighth nerve or renal function.

[d]Two-week regimen not intended for patients with known cardiac or extracardiac abscess or for those with creatinine clearance of <20 mL/minute, impaired eighth cranial nerve function or *Abiotrophia*, *Granulicatella*, or *Gemella* infection. Gentamicin nomogram should be used for preferred single daily dosing; when three divided doses are used, dosage should be adjusted to achieve peak serum concentrations of 3–4 μg/mL and trough serum concentrations of <1 μg/mL. Other potential nephrotoxic drugs should be used with caution in patients receiving gentamicin therapy.

[e]Vancomycin dosage should be reduced in patients with impaired renal function. In obese adult patients, a loading dose of 20 to 25 mg/kg based on actual body weight, with a maximum dose of 3000 mg, should be considered. Each dose of vancomycin should be infused for at least 1 hour to reduce the risk of the histamine-release red man syndrome. Peak and trough concentrations should be

measured to improve accuracy of vancomycin AUC_{24hr}/MIC and to optimize subsequent maintenance doses. Early and frequent monitoring of AUC values is recommended for maintenance dose adjustment.

Case 66-1, Question 4: When is determination of minimum bactericidal concentration (MBC) and minimum inhibitory concentration (MIC) useful in treating bacterial endocarditis?

In some IE cases, it is necessary to use two antibiotics to achieve synergistic activity against the organism. Once an organism is identified, its in vitro susceptibility pattern is determined by the MIC for various antibiotics. Standard Kirby–Bauer disk diffusion testing is inadequate in the setting of IE to aid in the selection of antibiotics without the quantitative information provided by the MIC.[1] In addition, the MBC may be useful in detecting tolerant strains, particularly in the setting of unexplained slow response or treatment failure. However, routine MBC determination is not recommended.[1] Treatment of endocarditis requires antibiotics with bactericidal activity; therefore, the serum concentration of the antibiotic must greatly exceed the MBC for the particular organism. For endocarditis caused by community-acquired VGS, this usually is achieved without much difficulty because most isolates are sensitive to penicillin at an MIC of <0.12 μg/mL[10]; corresponding MBCs are, at most, one or two tube dilutions higher.[14] The emergence of strains with resistance to penicillin and related β-lactams, such as ceftriaxone, is a significant problem, particularly among bloodstream isolates obtained from the nosocomial setting and patients with cancer having neutropenia.[14,21,22] The increasing prevalence of β-lactam–resistant

clinical isolates highlights the importance of determining the MIC and continued close monitoring of the antibiotic susceptibility of VGS.

Several studies have investigated whether vancomycin MIC was associated with treatment failure and mortality, and the data are mixed. Some studies showed suboptimal response and poor clinical outcome with vancomycin therapy for the treatment of invasive infection caused by MRSA strains with high vancomycin MIC of 2 μg/mL[23–28]; whereas others found no significant difference in clinical outcome such as mortality and infection recurrence when compared to MRSA strains with MIC of ≤1 μg/mL.[29,30] The heterogeneity of an individual's immune response may contribute to the different outcomes observed. Given the conflicting reports, vancomycin MIC alone should not be used to guide therapy decisions; instead, a patient's initial clinical response should determine whether to continue with vancomycin or switch to an alternative therapy.[31]

REGIMEN SELECTION

Case 66-1, Question 5: What factors must be considered in selecting a regimen for A.G.? Which regimen should A.G. receive?

Patients with endocarditis caused by penicillin-sensitive strains of VGS and non-enterococcal group D streptococci (eg, *S. gallolyticus*; MIC ≤0.12 μg/mL) can be treated with any one of three regimens, as outlined in the 2015 AHA treatment guidelines.[10] The suggested regimens (**Table 66-3**) are associated with cure rates of up to 98% and include (a) high-dose parenteral penicillin for 4 weeks, (b) high-dose parenteral ceftriaxone for 4 weeks, and (c) 2 weeks of combined therapy with high-dose parenteral penicillin and an aminoglycoside.[10,32–35] Ceftriaxone with an aminoglycoside for 2 weeks appears to be equally effective.[10,36]

HIGH-DOSE PENICILLIN FOR 4 WEEKS

Ten to 20 million units per day of IV penicillin G for 4 weeks resulted in a cure rate of 100% for 66 patients with non-enterococcal

streptococcal endocarditis.[33] Another study using penicillin monotherapy reported relapse in only 2 of 49 patients; however, both of these patients received <4 weeks of therapy.[34] The large range of 12 to 18 million units per day of penicillin is recommended to allow flexibility in dosing based on the patient's renal function and disease severity. Ampicillin IV (2 g every 4 hours) is a reasonable alternative.

SINGLE DAILY CEFTRIAXONE FOR 4 WEEKS

Ceftriaxone is active against viridans streptococcal strains isolated from patients with endocarditis. In one study, all 49 strains of VGS and 11 strains of *S. bovis* were inhibited at an MIC <0.125 µg/mL of ceftriaxone; one strain of *S. sanguinis* was inhibited at an MIC of 0.25 µg/mL.[37] Although no direct comparative trials have been performed evaluating ceftriaxone against high-dose penicillin for the treatment of streptococcal endocarditis, it appears to be comparable to high-dose penicillin when given for 4 weeks.[38],[39] Of 70 assessable patients who received ceftriaxone 2 g as a single daily dose for 4 weeks, all were cured, except for 1 patient who had a probable relapse 3 months after completion of therapy. Ceftriaxone inhibited all strains of VGS at an MIC of 0.25 µg/mL in both studies. Although the simplicity of single daily treatment with ceftriaxone is attractive for outpatient use, careful patient selection based on microbiologic, clinical, and host factors is critical to treatment success and proper and timely management of potential complications. (See Case 66-6, Question 1, for a detailed discussion of outpatient therapy.)

HIGH-DOSE PENICILLIN OR CEFTRIAXONE PLUS AN AMINOGLYCOSIDE FOR 2 WEEKS

The combination of 2 weeks of streptomycin (or gentamicin) with 4 weeks of penicillin is synergistically bactericidal for highly penicillin-susceptible and relatively penicillin-resistant streptococci, and enterococci (see Case 66-4, Question 4).[40],[41]A shortened combination regimen consisting of high-dose penicillin G and streptomycin for 2 weeks is an effective alternative to the previously described regimens. The reported cure rate in 104 patients treated at

the Mayo Clinic with this regimen was 99%.[40,42] Although clinical experience with combination therapy has been primarily with penicillin and streptomycin, in vitro and animal data support that streptomycin and gentamicin are reasonably interchangeable. Of note, streptomycin is rarely used presumably due to lack of clinician familiarity with this drug and laboratory access to streptomycin serum assays.[10] Administration of gentamicin once daily versus three times daily when added to penicillin appears equally effective in the treatment of VGS endocarditis.[32]

Combination therapy with once-daily ceftriaxone 2 g plus netilmicin or gentamicin at 3 mg/kg for 2 weeks has also been evaluated and clinical cure rates of 87% to 96% were observed in patients infected with penicillin-susceptible streptococci.[34,43] Although the aminoglycoside agent was administered as a single daily dose, all of the patients had measurable serum trough levels.[34,43] Therefore, the efficacy of "extended-interval dosing" of aminoglycoside (whereby trough levels are not detectable, allowing a drug-free interval) in short-course combination therapy remains uncertain. Based on available data, the 2-week regimen of penicillin or ceftriaxone plus an aminoglycoside appears to be efficacious for (rare) uncomplicated cases of highly penicillin-susceptible VGS and *S. gallolyticus* (MIC ≤0.12 µg/mL) native valve endocarditis. It is not recommended for patients with extracardiac complications or intracardiac abscesses, those with creatinine clearance <20 mL/minute, or those with impaired eighth cranial nerve function. Patients infected with *Abiotrophia*, *Granulicatella*, or *Gemella* spp. or those who have prosthetic valve infections should not receive short-course therapy.[10]

Patients with native valve endocarditis caused by relatively resistant VGS and *S. gallolyticus* with penicillin MIC >0.12 to <0.5 µg/mL should receive a 4-week regimen of high-dose penicillin plus 2 weeks of gentamicin (3 mg/kg IV every 24 hours). Alternatively, ceftriaxone (2 g IV every 24 hours) may be used alone for 4 weeks if the organism is susceptible to ceftriaxone. Patients allergic to β-lactams should receive vancomycin 15 to 20 mg/kg IV (based on actual body weight) every 8 to 12 hours for a duration of 4 weeks.[10]

SPECIAL CONSIDERATIONS

The risk of relapse may be higher in patients who have had symptoms for >3 months before the initiation of treatment. These patients should be treated with 4 to 6 weeks of penicillin combined with an aminoglycoside for the first 2 weeks.[1,10,38]

Abiotrophia defectiva and *Granulicatella* spp. (*G. elegans*, *G. adiacens*, *G. paraadiacens*, and *G. balaenopterae*), formerly known as nutritionally variant streptococci (NVS) are slow-growing, fastidious organisms that are responsible for ~5% of IE cases.[44] *A. defectiva* and *Granulicatella* spp. are less susceptible (MIC 0.2–2.0 μg/mL) or highly resistant (MIC >4 μg/mL) to penicillin when compared with other streptococci. In addition, many strains may be tolerant to penicillin.[14] Even in strains highly susceptible to penicillin, high rates of bacteriologic failure and relapse may occur in patients despite completion of the treatment course.[14] An animal model of endocarditis indicates that a penicillin–aminoglycoside (streptomycin or gentamicin) combination is significantly better than is penicillin alone in reducing bacterial counts.[45] Therefore, patients infected with *A. defectiva*, *Granulicatella* spp., and VGS with penicillin MIC ≥0.5 μg/mL should receive high-dose penicillin or ceftriaxone (2 g IV every 24 hours) in combination with gentamicin (1 mg/kg every 8 hours) for a duration of 4 to 6 weeks, usually determined with infectious diseases consultation.[10] A 6-week course of combination therapy with penicillin and gentamicin is recommended for patients with symptoms lasting >3 months in duration and for those with PVE caused by these strains.[10,14] Patients allergic to β-lactams should receive vancomycin 15 to 20 mg/kg IV (based on actual body weight) every 8 to 12 hours for a duration of 4 to 6 weeks.[10]

Assuming the isolated VGS strain from A.G. is not resistant to penicillin and he has no other complicating factors, any of the suggested regimens would be appropriate. Although A.G. has mild renal impairment, this is most likely secondary to the endocarditis and should improve once adequate antimicrobial therapy has been instituted. A.G. was begun on 12 million units per day of penicillin G, which would be reasonable for his age and mild renal impairment. If

nephrotoxicity were a major concern in A.G., ceftriaxone alone for 4 weeks is reasonable. If gentamicin is used, A.G.'s renal function should be monitored, and the dose should be adjusted appropriately if not using a single daily regimen. Multiple aminoglycoside dosing requires frequent monitoring for signs of toxicity by taking periodic peak and trough aminoglycoside concentrations.

STAPHYLOCOCCUS EPIDERMIDIS: PROSTHETIC VALVE ENDOCARDITIS

Etiology

CASE 66-2

Question 1: F.T., a 65-year-old male, presents with anorexia, fever, chills, and weight loss. His medical history is significant for replacement of his mitral and aortic heart valves (both porcine) 1 month ago for aortic stenosis, mitral regurgitation, and mitral stenosis secondary to rheumatic heart disease. Two weeks post discharge he presented to the emergency department (ED) with fever, a right pleural effusion, a pericardial friction rub, and pericarditis. The impression at that time was either post-pericardiotomy or Dressler syndrome. F.T. was sent home on anti-inflammatory agents but failed to improve. After continued symptoms of anorexia, nausea, chills, and fever of 101 °F (38.33 °C), he returned to the hospital. On readmission, his physical examination was noteworthy for a systolic ejection murmur at the left sternal border and 3+ pedal edema. Blood cultures were obtained, and routine laboratory studies were performed. His history and clinical presentation were strongly suggestive of PVE.

What are the most likely organisms responsible for PVE in F.T.?

PVE is a life-threatening infectious complication of artificial heart valve implantation that accounts for 7% to 25% of cases of IE in developed countries.[46–48] The prevalence of complications resulting in death has been as high as 20% to 40%.[47] The risk of PVE after surgery is ~1% at 12 months and 2% to 3% at 60 months. PVE is categorized as early or late, depending on the onset of clinical

manifestations after cardiac surgery.[46–48] Early PVE occurs within 2 months of surgery and is thought to represent infection by skin organisms implanted into the valve annulus (suture site where the valve is attached to cardiac muscle during valve placement).[46–48] The most common organisms cultured from patients such as F.T. with early PVE are coagulase-negative staphylococci (primarily *S. epidermidis* [>30%], most of which are resistant to methicillin), followed by *S. aureus* (20%), and gram-negative bacilli (10%–15%). Miscellaneous organisms, such as diphtheroids and fungi, account for the remainder. In contrast, streptococci are a more common cause of late PVE (>2 months after surgery).[46–48]

Prophylaxis

Case 66-2, Question 2: What measures can be taken to prevent early PVE?

The overall frequency of early PVE, despite antibiotic prophylaxis, is 1% to 4%.[49] Complications are severe and include valve dehiscence, acute heart failure, arrhythmias, and outflow obstruction. Although antibiotic prophylaxis before valve surgery (a "clean" procedure) does not seem to reduce the frequency of early PVE, it is indicated nevertheless because the complications of infection are catastrophic. The antimicrobial regimen used most commonly for cardiac surgery prophylaxis (see Chapter 63, Antimicrobial Prophylaxis for Surgical Procedures) consists of an antistaphylococcal cephalosporin, such as cefazolin, given in the operating room at the time of induction of anesthesia or in the 60 minutes before the procedure. Vancomycin is considered the prophylactic agent of choice for cardiovascular procedures, including prosthetic valve replacement and implantation of prosthetic grafts, for the following: (a) documented penicillin allergy, (b) prior receipt of broad-spectrum antimicrobial therapy and high likelihood of colonization with cephalosporin-resistant staphylococci or enterococci, or (c) performance of the procedure in a center

experiencing outbreaks or a high endemic rate of surgical infection with methicillin-resistant staphylococci.[50]

Antimicrobial Therapy

Case 66-2, Question 3: What are the treatment options for F.T.?

As noted earlier, F.T. most likely is infected with coagulase-negative staphylococci. For those rare coagulase-negative staphylococci that remain sensitive to β-lactams (<20%), a penicillinase-resistant penicillin (nafcillin or oxacillin) is the drug of choice (**Table 66-4**).[51] For the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci, vancomycin should be used.[51] Most staphylococci are sensitive to vancomycin with MIC of 2 μg/mL or less; however, strains of staphylococci with intermediate susceptibility to vancomycin have emerged.[52] Refer to the American Society of Health-System Pharmacists-Infectious Diseases Society of America (ASHP-IDSA) guidelines for area under the curve (AUC)-guided dosing and monitoring of vancomycin.[23]

Table 66-4
Treatment of Staphylococcal Endocarditis

Antibiotic	Dosage and Route	Duration
Without Prosthetic Material[a,b]		
Oxacillin/Methicillin-Susceptible Staphylococci		
Patients with Nonpenicillin Allergy		
Nafcillin *or* oxacillin	*Adult*: 2 g IV every 4 hours	6 weeks
	Pediatric: 150–200 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	
Patients with Penicillin Allergy		
Cefazolin[c] *or*	*Adult*: 2 g IV every 8 hours	6 weeks
	Pediatric: 100 mg/kg/24 hour IV (max: 6 g/24 hour) in equally divided doses every 8 hour	

Vancomycin[d,e,f]	*Adult*: 15–20 mg/kg every 8–12 hours (adjust dose based on AUC-guided monitoring)	6 weeks
	Pediatric (3 months to <12 years): 60–80 mg/kg/24 hour IV in four equally divided doses (max: 3g/24 hour; adjust dose based on AUC-guided monitoring) *Pediatric (≥12 years):* 60–70 mg/kg/24 hour IV in three to four equally divided doses (max: 3g/24 hour; adjust dose based on AUC-guided monitoring)	
Oxacillin/Methicillin-Resistant Staphylococci		
Vancomycin[d,e,f]	See abovementioned dosing of vancomycin in patients with penicillin allergy without prosthetic material	6 weeks
With Prosthetic Valve or Other Prosthetic Material[g]		
Oxacillin/Methicillin-Resistant Staphylococci		
Vancomycin[d,e,f]	See abovementioned dosing of vancomycin in patients with penicillin allergy without prosthetic material	≥6 weeks
With rifampin[h]	*Adult*: 300 mg IV/PO every 8 hours	≥6 weeks
	Pediatric: 20 mg/kg/24 hour PO (max: 900 mg/24 hour) in three equally divided doses	
With gentamicin[d,g,i]	*Adult*: 3 mg/kg IV or IM in two or three equally divided doses	2 weeks
	Pediatric: 3 mg/kg IV or IM in three equally divided doses	
Oxacillin/Methicillin-Susceptible Staphylococci		
Nafcillin *or* oxacillin[j,k]	*Adult*: 2 g IV every 4 hours	≥6 weeks
	Pediatric: 150–200 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	
With rifampin[h]	See prosthetic valve dosing for rifampin earlier	≥6 weeks
With gentamicin[d,g,i]	See prosthetic valve dosing for gentamicin earlier	2 weeks

IM, intramuscular; IV, intravenous; PO, orally.

[a]Antibiotic doses should be modified appropriately for patients with impaired renal function. Shorter antibiotic courses have been effective in some intravenous drug users (IVDUs) with right-sided endocarditis caused by *Staphylococcus aureus.* (See text for comments on the use of daptomycin and rifampin.)

[b]The benefit of additional aminoglycoside has not been established. The risk of toxic reactions because of these agents is increased in patients older than 65 years of age or those with renal or eighth nerve impairment.

[c]There is potential cross-allergenicity between penicillins and cephalosporins. Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin.

[d]Dosing of aminoglycosides and vancomycin on a milligram per kilogram basis will give higher serum concentrations in obese than in lean patients.

[e]Targeted area under the 24-hour plasma concentration–time curve to the minimum inhibitory concentration (AUC_{24hr}/MIC) ratio should be in the range of 400 to 600 mg*hour/L. (See text for detailed discussion on AUC-guided monitoring for vancomycin.) Each vancomycin dose should be infused for 1 hour.

[f]Vancomycin and gentamicin doses must be modified appropriately in patients with renal failure.

[g]Serum concentration of gentamicin should be monitored, and the dose should be adjusted to obtain a peak level of ~3 μg/mL.

[h]Rifampin is recommended therapy for infections caused by coagulase-negative staphylococci. Its use in coagulase-positive staphylococcal infections is controversial. Rifampin increases the amount of warfarin sodium required for antithrombotic therapy.

[i]Use during initial 2 weeks. (See text on alternative aminoglycoside therapy for organisms resistant to gentamicin.)

[j]First-generation cephalosporins or vancomycin should be used in patients with penicillin allergy.

[k]Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin and those infected with oxacillin-resistant staphylococci.

Infectious Diseases Pharmacists. *Am J Health Syst Pharm*. 2020;77(11):835–864. doi:10.1093/ajhp/zxaa036.

The AHA currently recommends the use of triple-drug combination (vancomycin, gentamicin, and rifampin) therapy for the treatment of PVE caused by methicillin-resistant, coagulase-negative staphylococci (methicillin-resistant *Staphylococcus epidermidis* [MRSE]).[10] Rifampin plays a role in the sterilization of the prosthetic material.[10,53–55] When isolates of MRSE are resistant to all available aminoglycosides, aminoglycoside treatment should be omitted. A fluoroquinolone that is active against the isolate may substitute for the aminoglycoside in the three-drug regimen. In addition to medical therapy, most patients also require valve replacement surgery.[46,47,51] Although alternative agents such as quinupristin/dalfopristin, linezolid, daptomycin, telavancin, ceftaroline, dalbavancin, and oritavancin have shown potent in vitro activity against coagulase-negative staphylococci, clinical experience in the treatment of IE caused by these strains is lacking.[51,56,57]

STAPHYLOCOCCUS AUREUS ENDOCARDITIS

Intravenous Drug User Versus Nonintravenous Drug User

CASE 66-3

Question 1: T.J., a 36-year-old human immunodeficiency virus (HIV)-seropositive male with a long history of IV drug abuse, was admitted to the hospital 4 months after being released from the state prison. His chief symptoms included fever, night sweats, pleuritic chest pain, shortness of breath, dyspnea on exertion, and fatigue. Physical examination was remarkable for a temperature of 101.2 °F (38.44 °C), splenomegaly, and a pansystolic ejection murmur at the left sternal border, best heard during inspiration. The chest radiograph revealed diffuse nodular infiltrates. TTE finding was positive for a small vegetation on the tricuspid valve leaflet. Significant laboratory results included the following:

WBC count, 14,000/μL with 65% polys and 5% bands

CD4 cell count, 350/μL
Hgb, 13.1 g/dL
Hct, 39%
ESR, 55 mm/hour (Westergren)

IE was suspected. Six samples of blood culture results were positive for coagulase-positive, gram-positive cocci, later identified as methicillin-sensitive *Staphylococcus aureus* (MSSA).

How do the clinical presentation and prognosis of endocarditis in an IVDU differ from that of a non-IVDU? What impact does HIV infection have on the risk and outcomes of endocarditis in an IVDU?

The incidence rate of endocarditis among IVDUs increased from 48 per 10,000 in 2002 to 79 per 10,000 persons in 2016 in the United States, attributable in part to the opioid epidemic.[6] The presentation, pathophysiology, and prognosis of endocarditis in IVDUs differ from those in non-IVDUs.[1,58,59] *S. aureus* is 10-fold more likely than are other pathogens to cause infection in this population.[10] *S. aureus* is part of the normal skin flora and is introduced when the illicit drug is injected. Compared to non-IVDUs with *S. aureus* endocarditis, IVDUs with *S. aureus* endocarditis are significantly younger; have fewer underlying diseases and more right-sided (tricuspid) involvement (in contrast to the predominance of left-sided disease in non-IVDUs); are less likely to have heart failure or central nervous system complications; and exhibit fewer signs of peripheral involvement and have a lower incidence of death.[59] Among patients without history of IV drug use, MRSA was involved in one-third of a cohort of 424 patients with definite *S. aureus* IE. Clinical features that characterized MRSA IE were persistent bacteremia, chronic immunosuppressive therapy, health care–associated infection (HAI), a presumed intravascular device source, and diabetes mellitus.[9] Prevalence of HIV seropositivity may be 40% to 90% among IVDUs with IE.[58,60] HIV-related immunosuppression may be an independent risk factor for the development of endocarditis.[61]

Antimicrobial Therapy

METHICILLIN-SENSITIVE STAPHYLOCOCCUS AUREUS

Case 66-3, Question 2: What are the therapeutic options for treating *S. aureus* endocarditis in T.J.?

The susceptibility of *S. aureus* to methicillin is the major determinant of antibiotic selection to treat T.J.'s endocarditis. T.J. is infected with MSSA. Therapy of choice for methicillin-sensitive strains is a penicillinase-resistant penicillin, such as nafcillin or oxacillin (Table 66-4).[10] Penicillin G rarely is appropriate because nearly all isolates of *S. aureus* produce penicillinase. A 6-week course of therapy with high-dose (12 g/day) oxacillin is the therapy of choice.[62,63] Vancomycin may be less efficacious than is oxacillin as an antistaphylococcal agent.[10,62] IVDUs, for the reasons previously identified, have a higher response rate to appropriate therapy compared with non-IVDUs.

IVDUs with uncomplicated right-sided endocarditis caused by MSSA have been treated successfully with a 2-week course of combination therapy with a penicillinase-resistant penicillin and an aminoglycoside.[64–67] In one study, 47 of 50 patients (94%) were cured after treatment with the combination of IV nafcillin (1.5 g every 4 hours) and tobramycin (1 mg/kg every 8 hours) for a total of 2 weeks. Notably, two of three patients treated with vancomycin relapsed, resulting in early termination of this arm of the study. Thus, vancomycin should not be used as a substitute for nafcillin in this regimen. An abbreviated treatment course is possible in a defined group of IVDUs with right-sided endocarditis with these characteristics: (a) clinical and bacteriologic response within 96 hours of initiation of therapy; (b) no evidence of hemodynamic compromise, metastatic infection, or neurologic or systemic embolic complications at either the initiation or completion of 2 weeks of therapy; (c) no echocardiographically demonstrable vegetations >2 cm^3; (d) not infected with MRSA; and (e) not receiving antibiotics

other than penicillinase-resistant penicillins, first-generation cephalosporins, and glycopeptides.[10],[66] HIV-seropositive patients (CD4 counts >300 × 10^6 cells) with tricuspid valve involvement included in the abovementioned studies also responded favorably to these short-course regimens; thus, a short-course regimen is an option for T.J.[66]

Recent studies suggest that the addition of an aminoglycoside to the treatment regimen does not improve the overall response for patients who meet the abovementioned criteria for short-course therapy and is associated with increased toxicity. Therefore, the AHA guidelines no longer favor the antibiotic combination. Also, all patients receiving the short regimen should be carefully evaluated for evidence of continuing infection or complications before discontinuing therapy at the end of the 2-week treatment course; extension of therapy with a β-lactam agent to at least a 4- to 6-week duration is recommended with any evidence of active disease or complications. Although the response to antibiotic therapy has been shown to be similar between asymptomatic HIV-seropositive and HIV-seronegative IVDUs, short-course therapy should be avoided in more immunosuppressed individuals (CD4 cell counts <200 μL) until more definitive outcome data are available in this subgroup.[58]

Oral regimen

An oral treatment regimen consisting of ciprofloxacin (750 mg every 12 hours) plus rifampin (300 mg every 12 hours) for 4 weeks has also been evaluated in IVDUs with uncomplicated right-sided endocarditis. In one small, noncomparative study, 10 IVDUs were successfully treated with ciprofloxacin (300 mg IV every 12 hours for the first 7 days followed by 750 mg orally [PO] every 12 hours for the remaining 21 days) in combination with rifampin (300 mg PO every 12 hours for 28 days).[68],[69] In another prospective study, IVDUs were randomized to receive oral ciprofloxacin plus rifampin versus standard parenteral therapy for 28 days.[69],[70] One of 19 patients in the oral group versus 3 of 25 patients in the parenteral group failed treatment; notably, approximately half of the study patients in either

group had possible endocarditis. Given the small number of patients who completed treatment, the comparative effectiveness between the oral and parenteral regimens will need confirmation in larger trials.[68–70] In addition, fluoroquinolone and rifampin resistance in *S. aureus*, compliance issues, and therapeutic monitoring in the outpatient setting are of concern.[68–70]

Other oral combination regimens have recently been evaluated in a randomized, multicenter noninferiority trial in Denmark.[71] The Partial Oral versus Intravenous Antibiotic Treatment of Endocarditis (POET) trial included 400 patients in stable condition with left-sided native and prosthetic valve IE due to *Streptococcus* spp. (*n* = 196), *E. faecalis* (*n* = 97), *S. aureus* (*n* = 87), or coagulase-negative staphylococci (*n* = 23). After receipt of standard IV treatment for at least 10 days and meeting criteria for clinical stability, patients were randomized to either continue with full IV treatment course (*n* = 199) or switch to an oral regimen (*n* = 201) consisting of two antibiotics from a different class and with moderate to high oral bioavailability. Clinical stability was defined as a temperature of <100.40 °F (<38 °C) for >48 hours, a decrease of C-reactive protein (CRP) to <25% of peak level or <20 mg/L, WBC count of <14,000/μL, and no sign of abscess or valve abnormalities requiring surgery seen on echocardiography. Patients were followed up until 6 months after completing their treatment to assess a composite end point of all-cause mortality, unplanned cardiac surgery, clinically evident embolic event, and relapse of bacteremia with the primary pathogen. The most common combination regimens were dicloxacillin 1 g PO four times daily plus rifampin 600 mg PO bid for *S. aureus*; amoxicillin 1 g PO four times daily plus moxifloxacin 400 mg PO once a day for *E. faecalis;* amoxicillin 1 g PO four times daily plus rifampin 600 mg PO bid for streptococci; and fusidic acid 750 mg PO bid plus linezolid 600 mg PO bid for coagulase-negative staphylococci. The primary composite outcome occurred in 12% of patients in the IV treatment group versus 9% of patients in the oral treatment group (odds ratio [OR] 0.72, 95% confidence interval [CI] [0.37–1.36]). A similar number of patients in each group had an unplanned cardiac surgery (3%), embolic event (1.5%), or relapse of bacteremia (2.5%).

Incidence of adverse events was similar in both groups. Notable limitations in this trial were that none of the patients had drug-resistant gram-positive cocci such as MRSA or vancomycin-resistant enterococci (VRE) as the causative pathogen, and only 20% of screened patients were included in the outcome analysis.[71] However, this study demonstrated that partial oral treatment in clinically stable patients with IE, with no signs of abscess or valve abnormalities, caused by susceptible streptococci, enterococci, and staphylococci was noninferior to full course of IV treatment.

Patients with penicillin allergy

Treatment of patients allergic to penicillin with *S. aureus* endocarditis is somewhat controversial. First-generation cephalosporins have been used with some success for the treatment of patients with mild penicillin allergy, but treatment failures with cefazolin are difficult to explain.[72] The stability of cefazolin when exposed to staphylococcal β-lactamase has been proposed as a mechanism for these failures.[73] Notably, staphylococci are capable of producing four β-lactamase (blaZ) subtypes A, B, C, and D, to which the stability of cefazolin varies.[74] These susceptibility differences are apparent on MIC testing only if a larger than usual inoculum is used (eg, $>10^6$ organisms).[73] It is possible that treatment failures with cefazolin are caused by a combination of the recalcitrant nature of the infection and the instability of cefazolin against a particular subtype of penicillinase produced by the staphylococcal strain, which is not readily detectable via routine MIC testing. For patients with endocarditis caused by *S. aureus* who have immediate-type hypersensitivity to penicillin, vancomycin or daptomycin may be used.[10]

Combination therapy

An enhanced response to combination therapy in the experimental animal model of MSSA endocarditis has prompted clinical trials to evaluate whether the addition of gentamicin to nafcillin confers any additional benefit. The combination of nafcillin and gentamicin resulted in more rapid clearing of organisms from the blood, but the

response rates were similar to that of patients treated with nafcillin alone.[62] As expected, the group receiving gentamicin had a higher incidence of nephrotoxicity. Thus, for the routine management of endocarditis caused by MSSA, the addition of a second drug does not appear to offer additional benefit when a penicillinase-resistant penicillin is used and is discouraged owing to the lack of clearly established efficacy and aminoglycoside toxicity (see Case 66-3, Question 2, previous discussion). For patients who remain bacteremic or who fail to improve clinically (usually non-IVDUs), imaging studies are often performed to identify metastatic sites of infection (ie, occult abscess) with possible need for surgical intervention.

METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS: VANCOMYCIN

Case 66-3, Question 3: How would T.J.'s therapy differ if he were infected with MRSA?

S. aureus IE involving MRSA has become increasingly common and accounts for up to 40% of cases.[7–9] Patients infected with MRSA are more likely to have chronic comorbid conditions (eg, diabetes mellitus, hemodialysis dependency) and HAI (76% vs 37%). They also more likely have an indwelling intravascular catheter or hemodialysis fistula as the presumed source of infection when compared with patients infected with MSSA (60% vs 31%).[7–9] Persistent bacteremia was more common with MRSA IE than with MSSA. In a recent prospective observational study, in patients with *S. aureus* IE, the median duration of bacteremia was 5 days (interquartile range [IQR], 3–8) for MRSA versus 4 days (IQR, 2–5) for MSSA. In this study, each additional day of bacteremia increased the risk of mortality by 16%.[75]

MRSA infection is traditionally associated with health care contact in the nosocomial setting, but it is now becoming more prevalent in the community (community-associated methicillin-resistant

Staphylococcus aureus [CA-MRSA]), especially in young and otherwise healthy individuals without the traditional risk factors.[9],[75],[76] CA-MRSA strains are distinct from health care–associated strains in that some strains possess a distinct virulence gene encoding for Panton-Valentine leukocidin (PVL). This pore-forming toxin causes severe necrosis in polymorphonuclear neutrophil cells in a rabbit model and has been associated with invasive infections, including necrotizing pneumonia and skin abscesses.[77–83] Specifically, CA-MRSA PVL-producing strains causing IE have been reported.[84] Although PVL plays a role in the virulence of certain MRSA strains, subsequent reports have demonstrated that the presence of PVL was not associated with disease severity or clinical outcome in patients presenting with infections due to CA-MRSA PVL-producing strains.[85–87]

Treatment options

Vancomycin has been the accepted standard of treatment for MRSA endocarditis. Response to treatment, however, is slower than that with semisynthetic penicillins (eg, nafcillin) for MSSA endocarditis. The mean duration of bacteremia in patients with MSSA endocarditis reportedly is 3.4 days for nafcillin alone and 2.9 days for the combination of nafcillin and gentamicin.[65] In contrast, the median duration of bacteremia for MRSA endocarditis was 7 days for vancomycin alone. Failure rates of up to 40% may occur in patients even with right-sided involvement. Of great concern is the emergence of resistant strains of *S. aureus* after repeated and prolonged exposure to vancomycin therapy.[52]

Either vancomycin or daptomycin at 8 mg/kg IV once daily (up to 12 mg/kg/day) may be used to treat patients with MRSA endocarditis.[31] The AHA recommends daptomycin 8 mg/kg/dose. Vancomycin 15 to 20 mg/kg IV based on actual body weight every 8 to 12 hours for a total of 6 weeks is recommended for adults with normal renal function. Traditionally, for serious MRSA infections (eg, endocarditis, bacteremia, meningitis, osteomyelitis, and pneumonia), the ASHP-IDSA guidelines recommended a target trough of 15 to 20

µg/mL as a surrogate for the ratio of the area under the 24-hour plasma concentration–time curve to the MIC (AUC_{24hr}/MIC) for vancomycin.[10,31] However, recent evidence demonstrated that a single trough level was not an optimal surrogate for determining AUC_{24hr}/MIC because of significant interpatient variability. Thus, the 2020 ASHP-IDSA vancomycin guidelines no longer recommend trough-only monitoring and instead recommend AUC-guided dosing, targeting an AUC_{24hr}/MIC ratio of 400 to 600 mg*hour/L, assuming that the *S. aureus* isolate has an MIC of 1 ug/ml from broth microdilution testing.[23] This range is recommended to maximize efficacy and minimize the risk of nephrotoxicity. The data to support the minimum AUC_{24hr}/MIC threshold of 400 mg*hour/L are based on studies of *S. aureus* bacteremia and endocarditis; however, the minimum needed for other gram-positive cocci or other sources of infections has yet to be clearly defined. AUC-guided monitoring requires the use of a Bayesian software program or the collection of two vancomycin concentrations obtained near steady state, a peak concentration at 1 to 2 hours postinfusion and a trough concentration at the end of the same dosing interval to estimate the 24-hour AUC.[23,88] Both methods used to estimate the AUC_{24hr}/MIC have been shown to significantly decrease the risk of vancomycin-induced nephrotoxicity compared to trough-guided monitoring[23,89,90]; however, whether attainment of AUC_{24hr}/MIC >400 mg*hour/L improves clinical outcomes in *S. aureus* endocarditis has not yet been demonstrated in prospective clinical trials.[23,88]

Persistent bacteremia

Case 66-3, Question 4: T.J. has been treated with vancomycin 1 g IV every 12 hours for 5 days for his MRSA endocarditis but does not seem to be clinically improving. His blood culture results are still positive, and his WBC count remains elevated at 12,500/µL with 55% polys and 7% bands. He continues to have a low-grade fever since starting vancomycin. His vancomycin AUC_{24hr}/MIC ratio on the second day of therapy was 417 mg*hour/L. The infected MRSA strain had a vancomycin MIC of 1.5 µg/mL as determined by the

Epsilometer test (E-test). What factors may be contributing to T.J.'s poor response to treatment? What other therapeutic options are available for T.J.?

In a large multinational study of nearly 1800 patients with definite IE, persistent bacteremia, receipt of vancomycin, and health care contact were significantly more common in patients with MRSA IE from the United States compared with those from other geographic regions.[6] The authors speculated that the higher rates of persistent bacteremia in U.S. patients are attributable in part to the receipt of vancomycin therapy. Vancomycin MIC values for *S. aureus* have been increasing over the years.[91] In response to increasing reports of vancomycin clinical failure caused by MRSA strains with high MIC values, the vancomycin breakpoint for susceptibility was reduced from 4 to 2 μg/mL for *S. aureus* in 2005 per the Clinical and Laboratory Standards Institute.[92],[93] Previous data have suggested that higher clinical failure rates in MRSA bacteremia were seen in patients treated with vancomycin when the MRSA isolate had a vancomycin MIC of 1.5 or 2 μg/mL compared to patients infected with MRSA isolates with MIC of 1 μg/mL or less[25–28]; however, a meta-analysis of 38 studies that included >8000 patients found no significant difference in mortality compared to those with MIC <1.5 μg/mL.[29] Another prospective cohort study involving >400 patients with *S. aureus* bacteremia, including 188 patients with MRSA bacteremia investigated whether the MIC value was a determinant of clinical outcomes. In the subgroup analysis for MRSA bacteremia that compared MIC of 2 μg/mL with MIC of <2 μg/mL, a higher MIC value was not associated with the composite outcome of bacteremia recurrence, all-cause readmission, and death at 30 and 90 days. Results from this study provided further support that vancomycin MIC at the higher end of the susceptibility range is not a primary determinant of treatment failure and is not associated with worse outcomes.[30]

Widespread use of vancomycin has led to the emergence of glycopeptide-intermediate *Staphylococcus aureus* (GISA) or heteroresistant glycopeptide-intermediate *Staphylococcus aureus* (hGISA) strains.[52] Reduced susceptibility to glycopeptides results

from an increase in the production of peptidoglycan precursors, leading to a thickened bacterial cell wall and decreased penetration of glycopeptides into the bacterial cell membrane.[94] An in vitro pharmacodynamic model demonstrated that vancomycin activity is also reduced in the presence of high inoculum.[95] In the absence of vancomycin, hGISA strains may revert to glycopeptide susceptibility, making it difficult to detect these strains in vitro. As such, several investigators have found that hGISA strains have an MIC range that overlaps with the currently defined susceptible range and that the prevalence among hospitalized patients is increasing.[96–98] Routine susceptibility testing methods performed in the clinical laboratory are unreliable in detecting MRSA strains with hGISA phenotype.[99] MIC determined by E-test best predicts treatment outcome with vancomycin.[23],[31],[100]

Despite attaining a goal AUC_{24hr}/MIC >400 mg*hour/L, T.J. fails to clinically improve and has persistent bacteremia. It is possible that T.J. is infected with an heteroresistant vancomycin-intermediate *Staphylococcus aureus* (hVISA) strain. IE is an infection with high bacterial load or large vegetation size. T.J. may have a vancomycin heteroresistant subpopulation that was undetected by microbiology laboratory and selected for in the setting of multiple prolonged courses of vancomycin treatment[101],[102]; thus, a change in therapy is warranted.

Daptomycin (Cubicin®) is a cyclic lipopeptide approved for the treatment of *S. aureus* bacteremia and right-sided endocarditis. In vivo, it has a wide spectrum of activity against gram-positive bacteria, including *S. aureus* (including MRSA), *E. faecalis*, *E. faecium*, streptococci, and most other species of aerobic and anaerobic gram-positive bacteria. It was approved for the treatment of *S. aureus* bacteremia and endocarditis in a noninferiority study in patients receiving daptomycin or standard therapy consisting of an antistaphylococcal penicillin or vancomycin in addition to low-dose gentamicin.[103] Successful outcome was seen in 46% (41 of 90) of patients who had presumed or definite staphylococcal endocarditis as their baseline diagnosis. Of those, MRSA endocarditis was

successfully treated in 42% (15 of 36) of cases. In patients with confirmed uncomplicated and complicated right-sided endocarditis, treatment success was similar between the daptomycin group (8 of 18) and the group receiving standard therapy (7 of 16) at 44%.

The use of daptomycin for the treatment of left-sided endocarditis is not established because only nine patients were treated and only one had treatment success. Daptomycin at >8 mg/kg/day for a total duration of 6 weeks should be used for the treatment of endocarditis. Considering its concentration-dependent effects, some recommended higher doses (up to 12 mg/kg/day) appear to be safe.[31],[104],[105] High-dose daptomycin should be considered in patients who have previously failed vancomycin treatment, who are severely ill, or who are infected with an isolate with elevated vancomycin MICs. Daptomycin should be dosed based on total body weight because patients with obesity have a larger volume of distribution as well as increased clearance compared with the nonobese population.[106] Creatine kinase levels should be obtained at baseline and weekly to monitor for elevations, and more frequently in patients who may be at risk for developing skeletal muscle dysfunction.[107] High-dose daptomycin at 8 to 12 mg/kg daily should be considered as an alternative therapy in T.J. Emergence of cross-resistance to daptomycin after vancomycin exposure has been documented.[108],[109] Similar to a thickened cell wall contributing to decreased susceptibility to vancomycin, the same mechanism is thought to contribute to daptomycin resistance in *S. aureus*.[110] Therefore, it is important to confirm MRSA susceptibility to daptomycin when used in a patient who had prior vancomycin exposure.

A potential treatment option for T.J., if his infected MRSA strain demonstrates reduced susceptibility to daptomycin, is the addition of an antistaphylococcal β-lactam agent such as nafcillin, oxacillin, or ceftaroline to daptomycin.[111],[112] Combining daptomycin with a β-lactam may enhance the binding effect of daptomycin, owing to the β-lactam altering the surface charge of MRSA.[111],[113] In a recent prospective study of 40 patients with MRSA bacteremia, the patients were given a combination of daptomycin plus ceftaroline versus vancomycin monotherapy, although it is unclear whether source

control was similarly performed in both groups. In a subgroup analysis of the seven patients with proven or suspected MRSA endocarditis, those who received vancomycin monotherapy had a significantly increased risk of mortality compared to those in the combination therapy group.[114] Although the results appeared promising, additional data involving a larger number of patients are needed before the combination can be recommended for routine use.

Addition of rifampin to standard treatment is not recommended for native valve endocarditis without secondary complications (eg, prosthetic joint, central nervous system involvement) given reports of worse outcomes and emerging resistance compared to rifampin-free regimens.[55],[115]

Once daptomycin therapy is initiated, continued monitoring of clinical response and organism susceptibility to daptomycin is warranted because resistance development has been reported during prolonged therapy.[116–118] Daptomycin MIC increase during therapy for *S. aureus* (especially MRSA) endocarditis was demonstrated in six patients. Baseline MIC increased from 0.25 to 2 μg/mL in five isolates, and from 0.5 to 4 μg/mL in one isolate.[117]

Linezolid (Zyvox®), an oxazolidinone, is not approved by the U.S. Food and Drug Administration (FDA) for the treatment of IE, but it has been used in cases of treatment failures, intolerability to standard therapy, or in infections with multidrug-resistant gram-positive cocci.[119] In a review article that included 33 case reports of IE treated with linezolid, 63.6% of patients had successful outcomes at the end of the follow-up period.[119] MRSA and vancomycin-intermediate *S. aureus* were the most common pathogens, accounting for 24% and 30% of cases, respectively. Failure with linezolid treatment was documented in seven cases, including four deaths attributed to endocarditis and three owing to persistent positive blood cultures. Thrombocytopenia was the most common adverse effect, occurring in eight of nine patients. In a compassionate-use program, linezolid achieved 50% clinical and microbiologic cure rates at 6-month follow-up in 32 patients with definite IE; MRSA was the causative agent in seven of those

patients. The most common adverse events reported in this group were gastrointestinal system effects and thrombocytopenia, each occurring in 15% of patients.[120] The degree of thrombocytopenia associated with linezolid correlates with the extent of drug exposure, as measured by area under the concentration curve and duration of treatment.[121] Of note, treatment failure with linezolid for MRSA endocarditis caused by persistent bacteremia has been described in two patients and in one patient with relapse of infection.[122],[123] Thus, additional efficacy data are needed before linezolid can be recommended for the treatment of IE caused by MRSA. Tedizolid (Sivextro®), a novel oxazolidinone, was shown to have only moderate bactericidal activity in vivo in a rabbit model of MRSA endocarditis and was less active than either vancomycin or daptomycin.[124] At this time, tedizolid cannot be recommended as a primary agent in the treatment of endocarditis.

ENTEROCOCCAL ENDOCARDITIS

Antimicrobial Therapy

ANTIBIOTIC SYNERGY

CASE 66-4

QUESTION 1: G.S., a 35-year-old female, has had anorexia, weight loss, and fever for the past 2 months. Her medical history is significant for an aortic aneurysm with insufficiency that resulted in an aortic valve replacement (porcine) 3 years before admission. Approximately 2 months before admission, G.S. had a cesarean section followed by tubal ligation. She did not receive antibiotic prophylaxis for either procedure. Physical examination revealed a thin female (60 inches [152.40 cm], 105.82 pounds [48 kg]) in no acute distress with evidence of a systolic heart murmur, splinter hemorrhages, and petechiae on her soft palate. Her temperature was 100.2 °F (37.88 °C). Her WBC count was 14,000/μL with a slight left shift; all other laboratory results were within normal limits. She was not taking any medications, and she has a documented allergy to penicillin (rash, urticaria, and wheezing). The working clinical diagnosis was

probable bacterial endocarditis, which was confirmed when four sets of blood cultures grew gram-positive cocci. Antibiotic therapy with gentamicin (50 mg IV every 8 hours) and vancomycin (1000 mg IV every 12 hours) was initiated. Biochemical testing subsequently identified the organism as *E. faecalis*, highly resistant to streptomycin (MIC >2000 µg/mL).

Why were two antibiotics prescribed for the treatment of enterococcal endocarditis in G.S.?

Enterococci, unlike streptococci, are inhibited but not killed by penicillin or vancomycin alone.[125,126] Relapse rates are unacceptably high if penicillin is used alone for the treatment of enterococcal endocarditis.[10,125,130] The synergistic combination of penicillin (or ampicillin, or piperacillin/tazobactam) or vancomycin with an aminoglycoside is required to produce the desired bactericidal effect.[127,128] The mechanism of synergy against enterococci is explained by an increased cellular uptake of the aminoglycoside with agents that inhibit cell wall synthesis (eg, β-lactams and vancomycin).[127] Numerous in vivo and clinical studies have confirmed the in vitro synergy for penicillin in combination with streptomycin or gentamicin for enterococcal endocarditis.[21,125–127] Because G.S. is allergic to penicillin, vancomycin was prescribed with an aminoglycoside.

Streptomycin resistance

Of the aminoglycosides, gentamicin and streptomycin are often tested with penicillin (or ampicillin) for synergistic bactericidal activity. As many as 55% of all enterococcal blood isolates are highly resistant to streptomycin (MIC >2000 µg/mL), and the combination of streptomycin with penicillin is not synergistic for those isolates. In contrast, gentamicin in combination with penicillin, ampicillin, or vancomycin is synergistic for most blood isolates of enterococci, regardless of their susceptibility to streptomycin.[1,125,128] In addition, ototoxicity in the form of vestibular dysfunction secondary to streptomycin therapy occurs in nearly 30% of patients in the treatment of enterococcal endocarditis and is most often irreversible. High peak concentrations and prolonged drug therapy have been

associated with ototoxicity, but laboratory assays for streptomycin levels are not readily available. Therefore, gentamicin in combination with penicillin (or ampicillin) or vancomycin is recommended by most authorities for the treatment of aminoglycoside-susceptible and, in particular, streptomycin-resistant enterococcal endocarditis, as it was for G.S.[10] Of note, other aminoglycosides cannot be used to substitute for gentamicin or streptomycin because of the uncertain correlation between in vitro synergy and in vivo efficacy.[10] **Table 66-5** lists the suggested regimens for the treatment of enterococcal endocarditis.

Table 66-5
Therapy for Endocarditis Caused by Enterococci (or Streptococci Viridans With an MIC $0.5 mg/mL)

Antibiotic[a,b]	Dose and Route	Duration
Patients with Nonpenicillin Allergy		
Penicillin G	*Adult*: 18–30 million units/24 hour IV given continuously or in six equally divided doses	4–6 weeks
	Pediatric: 300,000 units/kg/24 hour IV (max: 30 million units/24 hour) given continuously or in four to six equally divided doses	4–6 weeks
With gentamicin[c,d]	*Adult*: 1 mg/kg IM or IV every 8 hours	4–6 weeks
	Pediatric: 1 mg/kg IM or IV every 8 hours	4–6 weeks
Or		
Ampicillin	*Adult*: 12 g/24 hour IV given continuously or in six equally divided doses	4–6 weeks
	Pediatric: 300 mg/kg/24 hour IV (max: 12 g/24 hour) in four to six equally divided doses	4–6 weeks
With gentamicin[c,d] *or*	See nonpenicillin-allergic dosing for gentamicin earlier	4–6 weeks
With ceftriaxone	4 g/24 hour IV in two equally divided doses	6 weeks

Patients with Penicillin Allergye		
Vancomycin[f]	*Adult*: 15–20 mg/kg every 8–12 hours (adjust dose based on AUC-guided monitoring)	6 weeks
	Pediatric (3 months to <12 years): 60 to 80 mg/kg/24 hour IV in four equally divided doses (max: 3 g/24 hour; adjust dose based on AUC-guided monitoring) *Pediatric (≥12 years):* 60–70 mg/kg/24 hour IV in three to four equally divided doses (max: 3 g/24 hour; adjust dose based on AUC-guided monitoring)	6 weeks
With gentamicin[c,d]	*Adult*: 1 mg/kg IM or IV (max: 80 mg) every 8 hours	6 weeks
	Pediatric: 1 mg/kg IM or IV (max: 80 mg) every 8 hours	6 weeks

AUC, area under the curve; IM, intramuscular; IV, intravenous; MIC, minimum inhibitory concentration.

[a]Antibiotic doses should be modified appropriately in patients with impaired renal function.

[b]Enterococci should be tested for high-level resistance (gentamicin: MIC ≥500 µg/mL).

[c]Serum concentration of gentamicin should be monitored and dosage adjusted to obtain a peak level of ~3 µg/mL. (For shorter course gentamicin therapy for enterococcal endocarditis, see comment in text.)

[d]Dosing of aminoglycosides and vancomycin on a milligram per kilogram basis gives higher serum concentrations in obese than in lean patients.

[e]Desensitization should be considered; cephalosporins are *not* satisfactory alternatives.

[f]Targeted area under the 24-hour plasma concentration–time curve to the minimum inhibitory concentration (AUC_{24hr}/MIC) ratio should be in the range of 400 to 600 mg*hour/L. (See text for detailed discussion on AUC-guided monitoring for vancomycin.) Each dose should be infused over 1 hour; 6 weeks of vancomycin therapy recommended because of decreased activity against enterococci.

and the Society of Infectious Diseases Pharmacists. *Am J Health Syst Pharm*. 2020;77(11):835–864. doi:10.1093/ajhp/zxaa036.

Dual β-lactam combination

In light of the increasing prevalence of enterococci with high-level aminoglycoside resistance, the potential synergistic interaction between ampicillin or amoxicillin and a third-generation cephalosporin was explored in vitro and in experimental models of IE.[129] A bactericidal synergistic effect was shown between amoxicillin and cefotaxime against 50 strains of *E. faecalis*. Amoxicillin MIC decreased from 0.25 to 1 µg/mL to 0.01 to 0.25 µg/mL for 48 of 50 strains tested.[130] In addition, Brandt et al[131] demonstrated a synergistic bactericidal effect for amoxicillin in combination with imipenem against vancomycin–aminoglycoside-resistant *E. faecium* strains. The authors speculated that saturation of different penicillin-binding proteins by different β-lactam agents may be the underlying mechanism for the synergy observed. In an observational, nonrandomized multicenter study, 159 patients were treated with ampicillin (2 g IV every 4 hours) plus ceftriaxone (2 g IV every 12 hours) and 87 were treated with ampicillin plus gentamicin.[132] There were no differences in mortality (while on antibiotics and at 3-month follow-up), treatment failure, and relapses. In a subsequent retrospective study of 85 patients with *E. faecalis* IE, 18 patients were treated with the ceftriaxone-based combination and 67 patients with the gentamicin-based combination. The investigators found no significant difference in 1-year mortality or IE relapse between the ceftriaxone and gentamicin groups. One case of relapse occurred in each group after completion of treatment, 37 days and 210 days for the ceftriaxone- and gentamicin-based combination, respectively. Although this was a small retrospective study, it demonstrated results comparable to previous studies with regard to mortality and relapse of IE.[133] The 2015 AHA guidelines recommend double β-lactam therapy with ampicillin and ceftriaxone as a reasonable option for infections caused by aminoglycoside-resistant *E. faecalis* strains.

GENTAMICIN

Dosing

Case 66-4, Question 2: What is the optimal dosage of gentamicin for G.S.?

Because patients with enterococcal endocarditis require prolonged therapy with aminoglycosides, the optimal serum concentration should minimize toxicity without jeopardizing clinical cure. Early in vitro data indicated that the bactericidal activity of gentamicin against enterococci was not significantly different between peak concentrations of 5 and 3 μg/L; however, the differences between 3 and 1 μg/mL were significant.[129] Animal models of endocarditis show discordant results in bacterial counts per gram of vegetation in animals on low-dose versus high-dose aminoglycosides.[134,135] In experimental enterococcal endocarditis, multiple daily dosing is more effective than is single daily dosing in reducing bacterial titers in vegetations.[136–138] In contrast, VGS endocarditis can be managed with single daily dosing[43] (see Case 66-1, Question 4). Thus, single daily dosing of aminoglycosides is not recommended for the treatment of enterococcal endocarditis at this time.

The only study comparing high-dose (>3 mg/kg/day) and low-dose (<3 mg/kg/day) gentamicin with penicillin in humans with enterococcal endocarditis evaluated 56 patients during a 12-year period (36 with streptomycin-susceptible and 20 with streptomycin-resistant infections).[139] The relapse rate of patients infected with streptomycin-resistant organisms (n = 20) was not significantly different between the high- and low-dose treatment groups (n = 10 each). Furthermore, patients who received the higher doses of gentamicin experienced a greater prevalence of nephrotoxicity (10 of 10 vs 2 of 10; $P < .001$). Mean peak and trough concentrations of gentamicin in patients who received the high doses were 5 and 2.1 μg/mL, respectively; corresponding levels for patients receiving the low-dose regimen were 3.1 and 1 μg/mL.

Given the available data, it would be reasonable to start G.S. on a gentamicin dosage of 1 mg/kg every 8 hours (assuming her renal

function is normal) and to maintain peak concentrations of 3 to 5 μg/mL and trough concentrations of <1 μg/mL.

In combination with vancomycin

Case 66-4, Question 3: Why was vancomycin used in combination with gentamicin in G.S.? Is this combination effective against enterococci?

G.S. has a history of penicillin allergy. Most clinicians favor a combination of vancomycin and gentamicin for patients allergic to penicillin with enterococcal endocarditis.[10,125,139] The combination of vancomycin and gentamicin demonstrates bactericidal synergy for about 95% of enterococci strains. Because G.S. has PVE, she should receive ~15 to 20 mg/kg IV every 8 to 12 hours of vancomycin in combination with gentamicin (3 mg/kg/day) in divided doses. Serum concentrations of vancomycin and gentamicin should be monitored as previously discussed.

DURATION OF THERAPY

Case 66-4, Question 4: For how long should G.S. be treated?

Historically, enterococcal endocarditis has been treated with penicillin plus an aminoglycoside for 6 weeks, with an overall cure rate of about 85%.[10] Four weeks of therapy is probably adequate for most patients with enterococcal endocarditis.[10,139,140] One study evaluated the efficacy of a treatment regimen involving shorter course aminoglycoside therapy (median of 15 days) in combination with a cell wall–active agent for a median of 42 days in patients with PVE and native valve enterococcal endocarditis.[140] Clinical cure was observed in 75 of 93 (81%) patients overall, 78% of patients with PVE, and 82% of patients with native valves. Among those who had a clinical cure, 52% received a β-lactam, 12% received vancomycin, and 36% received a combination of both. Ampicillin was given in 88% of patients receiving a β-lactam. The causative organism was

E. faecalis in 78 patients and *E. faecium* in 5 patients. Clinical success was also achieved in all eight patients with native valve IE who received vancomycin (50%), ampicillin (25%), or a combination of both (25%) without synergistic aminoglycoside therapy.[140]

Patients with complicated courses should receive 6 weeks of therapy, including patients infected with streptomycin-resistant organisms (such as G.S.), those who have had symptoms for >3 months before the initiation of antibiotics, and patients with PVE (such as G.S.).[10],[17] Some clinicians recommend 6 weeks of therapy for all patients in whom the duration of illness cannot be firmly established (eg, many patients who present with subacute disease).

CASE 66-4, QUESTION 5: How do enterococci develop resistance to vancomycin? What are the therapeutic implications if G.S. is infected with glycopeptide-resistant enterococci?

GLYCOPEPTIDE RESISTANCE IN ENTEROCOCCI

VRE, particularly *E. faecium,* have emerged in the United States since 1987.[141],[142] The increased use of vancomycin since the mid-1980s has coincided with the increased resistance to this class of antibiotic. More recently, in a 2014 review of HAIs that included 4000 acute care hospitals in the United States, ~30% of enterococci were reported as vancomycin resistant.[143]

Although *E. faecalis* is responsible for 80% to 90% of infections caused by enterococci, *E. faecium* is more likely to exhibit resistance to glycopeptides compared with *E. faecalis*; >95% of VRE recovered in the United States are *E. faecium.* Glycopeptide-resistant enterococci synthesize abnormal peptidoglycan precursors that lower the binding affinity of glycopeptides to peptidoglycans.[140] VRE can be broadly classified into three separate phenotypes (A, B, and C) based on three structurally different genes and gene products (eg, altered ligases).[140] Most (~70%) of resistant enterococci are of the VanA phenotype, which are resistant to high levels of vancomycin (MIC >256 μg/mL). Expression of resistance is inducible, usually plasmid mediated, and transferable to other

organisms via conjugation. The VanB strains exhibit moderate vancomycin resistance (MIC 16–64 µg/mL), and the VanC strains are the least resistant (vancomycin MIC 8–16 µg/mL), because of chromosomal-mediated constitutive expression (eg, not inducible as are VanA and VanB); however, VanC isolates usually are associated with the much less common *E. gallinarum* and *E. casseliflavus* infections.

Vancomycin, extended-spectrum cephalosporins, and drugs with potent anti-anaerobic activity are risk factors for VRE.[140,144] Few therapeutic alternatives exist for VRE, and synergistic combinations are required for bactericidal activity and clinical cure in endocarditis. The treatment of choice is unknown, and practitioners must make decisions using the available data from in vitro synergy studies, experimental models of endocarditis, and scattered case reports. Of additional concern, glycopeptide-resistant isolates often exhibit concomitant high-level resistance to aminoglycosides and β-lactams (eg, ampicillin, penicillin) secondary to either β-lactamase production or alteration in the target penicillin-binding proteins. Several antibiotic combinations appear promising in vitro and in preliminary animal models of endocarditis, but few data are currently available in humans. Combination therapy with daptomycin plus ceftaroline or ampicillin have demonstrated successful synergy against VRE endocarditis in vitro via enhancement of the peptide cathelicidin LL37 activity, thereby increasing daptomycin surface binding to VRE.[145–147]

Streptogramin and oxazolidinone

Quinupristin/dalfopristin (Synercid®) and linezolid (Zyvox®) are two agents with activity and proven efficacy against some infections caused by VRE. Quinupristin/dalfopristin received accelerated approval by the FDA in late 1999 specifically for the treatment of vancomycin-resistant *E. faecium* bacteremia. However, in 2010, with other therapies available for the treatment of VRE, this FDA-labeled indication was removed. The fixed product is generally bactericidal against susceptible streptococci and staphylococci (including

methicillin-resistant strains), but it is bacteriostatic against *E. faecium.*

Linezolid has bacteriostatic activity against enterococci, including vancomycin-resistant *E. faecium* and *E. faecalis.* It is also active against other gram-positive cocci, including *S. pneumoniae* and methicillin-resistant staphylococci.[147] Vancomycin-resistant *E. faecium* isolates resistant to linezolid have been isolated.[148],[149] Treatment experience with linezolid under the compassionate-use protocol reported clinical and microbiologic cure rates of 50% at 6-month follow-up for patients with endocarditis. Vancomycin-resistant *E. faecium* was the causative organism for 19 of the 32 patients treated.[141] Common adverse effects associated with linezolid include nausea, headache, diarrhea, rash, and altered taste. Of greater concern is its potential to cause myelosuppression. Thrombocytopenia, leukopenia, anemia, and pancytopenia have all been reported. Up to 30% of treated patients experience thrombocytopenia (platelet counts <100,000 platelets/μL).[147] Linezolid given orally or via enteral feedings is completely bioavailable.[150] A dosage of 600 mg IV or orally twice daily for a duration >6 weeks is recommended for adults with IE caused by *Enterococcus* spp. strains resistant to penicillin, aminoglycosides, and vancomycin.[10] However, in a retrospective study of >600 patients with VRE bloodstream infections, including 39 patients with IE, linezolid therapy compared to daptomycin was associated with worse outcomes such as higher risk of treatment failure (adjusted relative risk [RR] 1.15, 95% CI [1.02–1.30]) and 30-day mortality (RR 1.17, 95% CI [1.04–1.32]).[151]

Daptomycin

Daptomycin has demonstrated activity against enterococci in vitro, with an MIC range of 0.25 to 4 μg/mL and MIC_{90} of 4 μg/mL for 219 vancomycin-resistant *E. faecium* isolates from the United States. For 40 vancomycin-resistant *E. faecalis* isolates, the MIC range was 0.015 to 2 μg/mL, with an MIC_{90} of 2 μg/mL. Of concern is the emergence of daptomycin resistance during therapy for VRE

infections.[152–154] In a patient with vancomycin-resistant *E. faecium* pyelonephritis, the initial isolate had an MIC of 2 µg/mL which increased to 32 µg/mL after 17 days of treatment.[155] There is a lack of clinical evidence to support the use of daptomycin monotherapy for multidrug-resistant enterococcal endocarditis. If daptomycin monotherapy is chosen, a higher dose of 10–12 mg/kg/day is recommended. Combination therapy with a higher dose of daptomycin plus ampicillin, ceftaroline, gentamicin, rifampin, or tigecycline can also be considered.[10]

FUNGAL ENDOCARDITIS CAUSED BY *CANDIDA ALBICANS*

Prognosis and Treatment

CASE 66-5

Question 1: B.G., a 35-year-old male heroin addict, was admitted to the hospital with pleuritic chest pain and dyspnea on exertion. Physical examination revealed a cachectic male with a temperature of 104 °F (40 °C), a diastolic regurgitant heart murmur heard loudest during inspiration, splenomegaly, and pharyngeal petechiae. On the chest radiograph, several pulmonary infiltrates with cavitation were evident. UA was significant for microscopic hematuria and RBC casts. A TEE demonstrated vegetations on both the tricuspid and aortic heart valves. B.G. had evidence of moderate heart failure, although his hemodynamic status at that time was "stable." Six sets of blood cultures were drawn over the course of 2 days, and broad-spectrum empiric coverage consisting of vancomycin, gentamicin, and ceftazidime was initiated. Two days later, two of the cultures grew *Candida albicans*, and a diagnosis of fungal endocarditis was established.

What is B.G.'s prognosis, and how should his fungal endocarditis be treated?

Fungal endocarditis is a rare but life-threatening infection that is difficult to diagnose and even more difficult to treat.[1] Most cases are caused by *Candida* and *Aspergillus* species. Fungal endocarditis

occurs primarily in IV drug users, patients with prosthetic heart valves, immunocompromised patients, those with IV catheters, or patients receiving broad-spectrum antibiotics.[156–159]

Management of fungal endocarditis generally requires early valve replacement and aggressive fungicidal therapy with liposomal amphotericin B (3–5 mg/kg IV daily) with or without 5-flucytosine (5-FC) (25 mg/kg orally qid), or monotherapy with a high-dose echinocandin (micafungin 150 mg IV daily, caspofungin 150 mg IV daily, or anidulafungin 200 mg IV daily).[160]

These antifungal agents should be prescribed for B.G., and his broad-spectrum antibiotic should be discontinued. B.G.'s clinical presentation and chest radiograph indicate that fragments of vegetation have already embolized to his lungs and possibly to other vital organs (eg, spleen, kidneys). Because of the morbidity and mortality associated with major emboli and valvular insufficiency, B.G. should undergo surgery within 48 to 72 hours of starting antifungal therapy. The prognosis for B.G. is dismal even with proper medical and surgical treatment. In a series analyzing 270 cases of fungal IE occurring during a 30-year period, mortality for those who received combined medical and surgical management was 45%, compared with 64% for those who received antifungal therapy alone.[156] Despite initial response to treatment, the rate of relapse is high (30%–40%), and relapse can occur up to 9 years after the initial episode of infection.[156–159] Most deaths in IVDUs with endocarditis are secondary to heart failure, a finding already evident in B.G.[1] In addition, replacement of a heart valve for fungal endocarditis in a heroin addict carries a significant risk of late morbidity and mortality.[156]

COMBINATION THERAPY WITH 5-FLUCYTOSINE AND AMPHOTERICIN B

Case 66-5, Question 2: Why is it important to treat B.G.'s fungal endocarditis with the combination of 5-FC and lipid-based amphotericin B? What is the optimal duration of therapy?

The poor prognosis associated with fungal endocarditis warrants the administration of 5-FC in combination with amphotericin B, despite its potential for causing bone marrow suppression and hepatotoxicity.[156] The vegetations from B.G.'s tricuspid or aortic heart valves already have broken off and caused pulmonary cavitation and, possibly, splenomegaly. His clinical presentation is consistent with a potentially fatal outcome; therefore, his blood isolates should be tested for in vitro susceptibility to amphotericin, 5-FC, and azoles. Fungi resistant to 5-FC alone may still be susceptible to the synergistic effect of the 5-FC–amphotericin B combination.[161] If the organism is resistant to 5-FC, in vitro synergy testing between these two antifungals should be performed or therapy with an echinocandin is warranted. The optimal dose and duration of antifungal therapy for fungal endocarditis have not been determined by clinical studies; however, postoperative treatment with liposomal amphotericin B (3–5 mg/kg IV daily) and 5-FC (25 mg/kg orally qid) for a minimum of 6 weeks is recommended.[160,162]

In patients with fungal PVE, some experts advocate secondary prophylaxis for a minimum of 2 years or lifelong suppressive treatment with an oral antifungal agent for nonsurgical candidates in light of the high rates of relapse.[1,156,158,161–164] Nephrotoxicity caused by amphotericin B is often a serious dose-limiting factor to completion of therapy, particularly in patients who require a prolonged treatment course. Renal dysfunction secondary to the conventional formulation of amphotericin B may stabilize or improve with the switch to lipid-formulated amphotericin B products (eg, Abelcet®, AmBisome®).[165] In addition, the lipid formulation appears more potent against *Candida* biofilm in vitro.[166,167]

ALTERNATIVE ANTIFUNGALS

Case 66-5, Question 3: If B.G. experiences significant toxicities because of prolonged combination treatment with amphotericin and 5-FC, what alternative antifungal agent(s) can be used to treat his fungal endocarditis?

Alternative antifungal agents, including echinocandins and azoles, are potential options in patients who experience significant renal toxicities. Echinocandins are fungicidal against most *Candida* species, including those in biofilms. A limited, but growing, number of case reports and small observational studies describe successful outcomes with use of the echinocandins in patients with *Candida* IE. An echinocandin-based treatment with caspofungin, micafungin, or anidulafungin was found to be as effective and with similar mortality rate as an amphotericin-based regimen.[168–171]

Another alternative is fluconazole (Diflucan®), a triazole compound that is active against *Candida* species, particularly *C. albicans* and *C. parapsilosis.* It also has a favorable toxicity profile compared with amphotericin and 5-FC.[172] Successful outcome with fluconazole treatment of fungal endocarditis in humans has been described in only a few case reports.[173–176] Patients with various *Candida* species were treated with 200 to 600 mg of fluconazole daily for 45 days to 6 months or until death. Fluconazole therapy reduced or completely removed all cardiac vegetations and resolved clinical symptoms. Because of the lack of adequate clinical experience, however, the use of fluconazole in treating fungal endocarditis cannot be advocated except in patients who require lifelong therapy because of the following situations: (a) The patient is a poor surgical candidate, (b) the patient has relapsed at least once since the initial infection episode, or (c) the patient has PVE.

Gram-Negative Bacillary Endocarditis Caused by *Pseudomonas aeruginosa*

Risk Factors

Case 66-5, Question 4: Fourteen months after completing his course of antifungal therapy, B.G. was readmitted to the hospital with a 48-hour history of fever, shaking chills, rigors, and night sweats. His vital signs at that time were

blood pressure, 100/60 mm Hg; pulse, 120 beats/minute; respirations, 24/minute; and temperature, 103.70 °F (39.83 °C). A new-onset systolic murmur was noted on auscultation. Two-dimensional echocardiography revealed two small vegetations on the prosthetic valve. Empiric therapy consisting of amphotericin B, 5-FC, vancomycin, and gentamicin was initiated. Three blood cultures drawn on the day of admission had positive findings for *P. aeruginosa* with the following antibiotic susceptibilities: gentamicin (8 µg/mL), tobramycin (2 µg/mL), piperacillin–tazobactam (16 µg/mL), and ceftazidime (2 µg/mL). A presumptive diagnosis of PVE caused by *P. aeruginosa* was made. Was the finding of *Pseudomonas* expected in B.G.?

Gram-negative endocarditis is commonly associated with health care exposure, especially in patients with prosthetic heart valves, and less commonly now in IVDUs.[10] Most gram-negative endocarditis cases are caused by *Pseudomonas* species, *S. marcescens*, and *Enterobacter* species, although numerous other gram-negative organisms have been known to cause endocarditis.[177–180]

Antimicrobial Therapy

Case 66-5, Question 5: How should B.G.'s gram-negative endocarditis be treated and monitored?

The previous empirical antimicrobials should be discontinued because *P. aeruginosa* has been cultured from B.G.'s blood. A bactericidal combination of antibiotics usually is required to provide in vivo synergy and to prevent resistant subpopulations from emerging during therapy.[1,181] Endocarditis caused by *P. aeruginosa* (as in B.G.) should be treated for at least 6 weeks with a combination of an aminoglycoside and an antipseudomonal penicillin (piperacillin–tazobactam) or cephalosporin (eg, ceftazidime).[1,10,180,182–184] B.G., therefore, should be treated with ceftazidime (2 g IV every 8 hours) with concurrent high-dose tobramycin (5–7 mg/kg IV every 24 hours). Aminoglycosides (tobramycin or gentamicin) at high-dose extended interval should

achieve peak and trough serum concentrations of 15 to 20 μg/mL and <2 μg/mL, respectively, to ensure maximum efficacy, in conjunction with surgical excision of the infected valve.[1,10]

There is very limited clinical data regarding the use of other antipseudomonal antibiotics such as imipenem, meropenem, aztreonam, and ciprofloxacin in the treatment of endocarditis.[185–188] Newer β-lactam and β-lactamase combinations (eg, ceftolozane/tazobactam [Zerbaxa®], ceftazidime/avibactam [Avycaz®]) meropenem/vaborbactam [Vabomere®], imipenem-cilastatin/relebactam [Recarbrio®]) as well as cefiderocol (Fetroja®) may be considered as alternative treatment options for multidrug-resistant *Pseudomonas* infections based on documented in vitro susceptibility. However, their efficacy for the treatment of endocarditis has not yet been demonstrated.

CULTURE-NEGATIVE ENDOCARDITIS

CASE 66-5, QUESTION 6: B.G.'s history, clinical presentation, and imaging studies are strongly suggestive of IE. If his blood culture results had been negative after 48 hours of incubation, the working diagnosis would have been culture-negative endocarditis. What are the possible reasons for culture-negative endocarditis, and what measures should be taken to establish a microbiologic etiology?

Culture-negative endocarditis occurs in 5% to 20% of patients, which may be due to inappropriate microbiologic culture techniques, prior administration of antimicrobials, slow-growing and fastidious organisms, such as gram-negative bacilli in the *Haemophilus–Actinobacillus–Cardiobacterium–Eikenella–Kingella* (HACEK) group, *Brucella*, *Coxiella*, *Chlamydiae*, strict anaerobes, and fungi. Other diagnostic tests such as special culture media, serologic or polymerase chain reaction (PCR) tests can be used to identify difficult-to-cultivate organisms.[10,189] Of note, previously, *Abiotrophia* has been the cause of most of the cases of endocarditis diagnosed

as culture negative, initially because of its requirement for the addition of vitamin B_6 (pyridoxal HCl) to the culture media for laboratory growth; however, laboratory identification is no longer a significant problem with current culture media and laboratory techniques.[14]

Empiric Therapy

Case 66-5, Question 7: Considering that the causative organism remains unidentified, what antimicrobial regiment do you recommend for the empiric treatment of B.G.'s presumed culture-negative endocarditis?

In the hemodynamically stable patient, antibiotic therapy should be withheld until positive blood cultures are obtained.[1] Based on B.G.'s clinical presentation and echocardiographic findings, empiric antibiotics should be initiated as soon as necessary cultures have been collected. Because staphylococci (often MRSA) and gram-negative bacilli account for most cases of endocarditis in IVDUs with a prosthetic heart valve, B.G. should be started on a broad-spectrum four-drug regimen: vancomycin targeting an AUC_{24hr}/MIC ratio of 400 to 600 mg*hour/L, gentamicin targeting a peak of 3 to 4 µg/mL, cefepime 2 g IV every 8 hours, and rifampin 300 mg IV/PO every 8 hours.[10,19] Depending on the gram-negative pathogens common to the region and their anticipated susceptibilities, a third-generation cephalosporin (ceftriaxone or ceftazidime) or piperacillin–tazobactam could be used. The combination of an aminoglycoside with piperacillin–tazobactam also will provide coverage for enterococci. Because B.G. may be experiencing a relapse caused by *C. albicans*, the addition of liposomal amphotericin B and 5-FC would be appropriate.

B.G.'s clinical status and the positive echocardiogram finding indicate that early surgical valve excision and replacement are necessary. Cultures obtained from the excised valve may allow for identification of the causative organism and subsequent alteration of his antimicrobial regimen depending on susceptibilities.

PROPHYLACTIC THERAPY

Rationale and Recommendations

CASE 66-6

QUESTION 1: B.B., a 74-year-old male with poor dentition, is scheduled to have all his remaining teeth extracted for subsequent fitting of dentures. His medical history is significant for numerous infections of the oral cavity and prosthetic valve replacement 2 years ago. His only current medications are oral digoxin (Lanoxin®) 0.125 mg/day and furosemide (Lasix®) 40 mg every morning and he has no known drug allergy.

What is the rationale for antibiotic prophylaxis?

Because IE is associated with significant mortality and long-term morbidity, prevention in susceptible patients is of paramount importance.[1] Estimates are, however, that <10% of all cases are preventable.[190] The incidence of endocarditis in patients undergoing procedures known to cause significant bacteremia, even without antibiotic prophylaxis, is low. In addition, endocarditis may develop after the administration of seemingly appropriate chemoprophylaxis. Therefore, it is not surprising that the efficacy of prophylaxis has never been established through placebo-controlled clinical trials. Approximately 6000 patients would be necessary to demonstrate a statistical difference (if one exists) between untreated controls and a group receiving prophylaxis.[191] Without conclusive clinical data from prospective trials, recommendations for antibiotic prophylaxis are based largely on in vitro susceptibility data, evaluation of antibiotic regimens using animal models of endocarditis, and anecdotal experiences.[191] Prophylactic antibiotics are thought to provide protection by decreasing the number of organisms reaching the damaged heart valve from a primary source. Thus, antibiotics theoretically prevent bacterial multiplication on the valve and interfere with bacterial adherence to the cardiac lesion.[191]

The 2007 AHA recommendations for antibiotic prophylaxis before common medical procedures are outlined in **Table 66-6**.[191] Compared with previous (1997) guidelines, the current guidelines only recommend the use of prophylaxis in patients with specific cardiac conditions (associated with the highest risk of adverse outcomes from endocarditis) who are undergoing only dental or respiratory tract procedures. The use of prophylaxis for patients undergoing genitourinary or gastrointestinal procedures is not recommended because of a continuing lack of evidence to support efficacy.

Table 66-6

Cardiac Conditions for Which Prophylaxis Is Recommended

Cardiac Conditions

▪ Prosthetic cardiac valves
▪ Previous bacterial endocarditis
▪ Congenital heart disease
  ▪ Unrepaired cyanotic CHD, including palliative shunts and conduits
  ▪ Completely repaired congenital heart defect with prosthetic material device during the first 6 months after the procedure
  ▪ Repaired CHD with residual defects at or adjacent to the site of the prosthetic device or patch
  ▪ Mitral valve prolapse with valvular regurgitation and/or thickened leaflets
▪ Cardiac transplantation recipients who develop cardiac valvulopathy

CHD, congenital heart disease.

Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation*. 2007;116(15):1736–1754.

DENTAL AND UPPER RESPIRATORY TRACT PROCEDURES

Analysis of published data shows that VGS bacteremia can result from any procedure that involves the manipulation of the gingival tissue or the periapical region of the teeth or perforation of the oral

mucosa. Placement or removal of prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, taking dental radiographs, bleeding from trauma to the lips or oral mucosa, and instantaneous shedding of deciduous teeth do not require chemoprophylaxis. Endotracheal intubation also does not require prophylactic therapy.

Antimicrobial prophylaxis should be directed against VGS because these organisms are the most common cause of endocarditis after dental procedures. Invasive surgical procedures involving the upper respiratory tract, such as incision or biopsy of the respiratory mucosa (eg, tonsillectomy, adenoidectomy), can cause transient bacteremia with organisms that have similar antibiotic susceptibilities to those that occur after dental procedures; therefore, the same regimens are suggested. Prophylaxis is not recommended for bronchoscopies unless the procedure involves incision of the respiratory mucosa. Amoxicillin is the current recommendation for oral prophylaxis in susceptible persons having dental or upper respiratory tract surgery. Oral clindamycin, clarithromycin, or azithromycin are alternatives for patients with immediate-type hypersensitivity reaction to penicillins. Only patients with outlined cardiac conditions should receive prophylactic antibiotics.

Most cases of endocarditis caused by bacterial flora from the mouth do not follow dental procedures but rather are the result of poor oral hygiene. The cumulative exposure to random bacteremias from daily oral activities is estimated to be 5730 minutes during a 1-month period compared with only 6 to 30 minutes for a dental procedure. Furthermore, the cumulative exposure to bacteremia from routine daily activities may be up to 5.6 million times greater than a single tooth extraction.[191] Based on the study results, concerns for antimicrobial resistance, and cost, changes to restrict the use of antibiotic prophylaxis before dental procedures to the highest risk patients may be expected with future AHA guidelines.

Indications and Choice of Agent

Case 66-6, Question 2: Is prophylactic antibiotic therapy indicated for B.B.? If so, which antibiotic(s) should be used?

Based on the current recommendations, B.B. is a candidate for antibiotic prophylaxis. Presence of a prosthetic aortic valve while undergoing multiple tooth extractions, procedures likely to result in bacteremia, places him at high risk for experiencing endocarditis. According to **Table 66-7**, B.B. should receive a single 2-g oral dose of amoxicillin 1 hour before the procedure.

Table 66-7
Endocarditis Prophylaxis Regimen Indicated for Patients With Cardiac Conditions

Drug[a]	Dose
DENTAL or UPPER RESPIRATORY TRACT PROCEDURES	Single dose 30–60 minutes before the procedure
Standard Oral Regimen	
Amoxicillin	*Adult*: 2 g
	Pediatric: 50 mg/kg
Allergic to Penicillin or Ampicillin	
Clindamycin	*Adult*: 600 mg
	Pediatric: 20 mg/kg
Cephalexin[b,c]	*Adult*: 2 g
	Pediatric: 50 mg/kg
Azithromycin or clarithromycin	*Adult*: 500 mg
	Pediatric: 15 mg/kg
Unable to Take Oral Medications	
Ampicillin	*Adult*: 2 g IM or IV
	Pediatric: 50 mg/kg IM or IV
Allergic to Penicillin or Ampicillin	
Clindamycin	*Adult*: 600 mg IM or IV
	Pediatric: 20 mg/kg IV

Cefazolin[b]	*Adult*: 1 g IM or IV
	Pediatric: 50 mg/kg IM or IV

IM, intramuscular; IV, intravenous.

[a]See Table 66-6.

[b]Cephalosporins should not be used in individuals with immediate-type hypersensitivity reaction (eg, urticaria, angioedema, or anaphylaxis) to penicillin or ampicillin.

[c]Other first- or second-generation oral cephalosporins in equivalent adult or pediatric dose.

Respiratory Tract Infections

Jason Cross, Evan Horton, and Dinesh Yogaratnam

CORE PRINCIPLES	CHAPTER CASES
ACUTE BRONCHITIS	
1 Acute bronchitis is a commonly encountered clinical diagnosis exhibited by cough for more than 5 days and generally does not require treatment with antimicrobial agents.	**Case 67-1 (Questions 1-7)**
ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE	
1 Antibiotics should be provided to patients with acute exacerbations of chronic obstructive pulmonary disease (AECOPD) if three primary symptoms (increased dyspnea, increased sputum volume, and increased sputum purulence) are present, if two primary symptoms are present and increased sputum purulence is one of the	**Case 67-2 (Question 3, 4)**

	symptoms, or if mechanical ventilation is required.	
2	Hospitalized patients with AECOPD should both be optimally treated and their chronic obstructive pulmonary disease (COPD) management should be assessed to decrease the likelihood of readmission. Baseline COPD medications should be reviewed and adjusted based on disease severity. Additionally, an assessment of patients' understanding of the role of medications (maintenance therapy vs rescue medications), their ability to use inhalers correctly and access to prescribed medications, and discussions regarding pulmonary rehabilitation should take place. Pharmacologic venous thromboembolism prophylaxis should also be considered in this high-risk population.	**Case 67-2 (Question 1, 2, 5, 6)**
3	Vaccinations against influenza and *Streptococcus pneumoniae* in patients with COPD or with previous pneumonia reduce disease-associated morbidity.	**Case 67-2 (Question 7)**
	COMMUNITY-ACQUIRED PNEUMONIA	
1	The first decision after a diagnosis of community-acquired pneumonia (CAP) is to determine the need for hospitalization and severity of disease. Several predictive rules including the pneumonia severity index (PSI) and CURB-65 (confusion, uremia, increased respiratory rate, low blood pressure, and age ≥65 years) have	**Case 67-3 (Question 2)**

	been developed to facilitate site-of-care decision-making.	
2	The most frequently isolated bacterial pathogen causing CAP, regardless of epidemiologic factors and severity of illness, is *S. pneumoniae.*	**Case 67-3 (Question 4)**
3	The most important consideration when selecting empiric therapy is to identify patients at risk for infection with drug-resistant *S. pneumoniae* (DRSP).	**Case 67-3 (Question 5)**
4	Patients who continue to have a positive laboratory test result for influenza more than 48 hours after the onset of illness are at high risk of requiring hospitalization; those who are not improving should be treated.	**Case 67-4 (Question 2)**
	HOSPITAL-ACQUIRED AND VENTILATOR-ASSOCIATED PNEUMONIA	
1	Hospital-acquired pneumonia (HAP) is defined as pneumonia that occurs at least 48 hours after hospital admission. Ventilator-associated pneumonia (VAP) refers to pneumonia that arises 48 to 72 hours after endotracheal intubation.	**Case 67-5 (Question 1)**
2	The major difference in the bacteriology between CAP and HAP/VAP is a shift to gram-negative pathogens, multidrug-resistant (MDR) pathogens, and methicillin-resistant *Staphylococcus aureus* (MRSA) in HAP/VAP.	**Case 67-5 (Question 1)**
3	Risk factors for pneumonia caused by	**Case 67-5**

	MDR pathogens include antimicrobial therapy in the previous 90 days, current hospitalization of 5 days or more, or immunosuppressive disease or therapy.	**(Question 1)**
4	Patients with early-onset pneumonia (<5 days) and no MDR risk factors can be treated with a single agent, including a non-antipseudomonal third-generation cephalosporin or ertapenem, ampicillin/sulbactam, or an antipneumococcal fluoroquinolone. Empiric therapy in those with late-onset pneumonia (≥5 days) or MDR risk factors should include a combination of antibiotics active against *Pseudomonas aeruginosa.* This regimen usually includes an antipseudomonal β-lactam, plus either an aminoglycoside or ciprofloxacin/levofloxacin. Vancomycin or linezolid should be added if MRSA risk factors are present or if there is a high incidence at the health care facility.	**Case 67-5 (Question 2)**

ACUTE BRONCHITIS

Definition and Incidence

Acute bronchitis (AB) is defined as an acute, self-limiting respiratory illness of the upper bronchi accompanied by cough for more than 5 days.[1–3] AB may be associated with or without purulent sputum production, and fever is rare.[2] Patients may be diagnosed with AB when there is no evidence of pneumonia and when acute asthma, an acute exacerbation of chronic obstructive pulmonary disease

(AECOPD), or the common cold have been ruled out as the cause of cough.[3] Although the true incidence of AB is unknown, it is considered to be one of the most common conditions encountered in clinical practice, accounting for ~7.7 million outpatient visits per year.[1,4]

Pathophysiology and Epidemiology

AB is characterized by the inflammatory response to infection in the epithelium of the bronchi. Further progression of this inflammation leads to thickening of the tracheal mucosa.[1,2] Sloughing of cells from the tracheobronchial epithelium and inflammatory mediators causes bronchospasm and reduced forced expiratory volume in 1 second (FEV_1) that usually improves after 5 weeks. Spread of pathogen and inflammatory response correlate with patient symptoms. Although bacteria can be isolated from sputum, bacterial invasion of the bronchial tree rarely occurs, and the role of bacterial pathogens in AB is limited.[5] The vast majority of cases of AB are presumed to be caused by viruses.[2,5–7]

Clinical Presentation

Cough lasting for more than 5 days is the hallmark sign of AB. Although the illness is self-limited, cough can last for up to 3 weeks (typical duration 10–20 days). Sputum production occurs in up to 50% of cases, but it does not indicate bacterial infection.[3] Fever is unusual in most cases; when present, it should prompt investigation for influenza (during appropriate seasons) or for pneumonia (if other clinical signs are present).

Overview of Drug Therapy

CASE 67-1

Question 1: A.R. is a 50-year-old male presenting with a cough. His symptoms have persisted for 8 days, and he now produces yellow sputum with each cough. He has had no recent illnesses; however, his 14-year-old son in high school has experienced recent mild colds. A.R. denies nausea, vomiting, or fever and chills. A review of systems reveals fatigue and difficulty sleeping because of cough. Past medical history includes hypertension managed with lisinopril and hyperlipidemia for which he takes atorvastatin. He also takes low-dose aspirin for stroke prevention. Vital signs indicate a temperature of 98.78 °F (37.1 °C), heart rate of 70 beats/ minute, blood pressure of 130/70 mm Hg, and respiratory rate of 18 breaths/minute with accompanying oxygen saturation of 98% on room air. His physical examination is normal, except for positive for coarse breath sounds that clear with coughing.

What signs and symptoms in A.R. are consistent with AB?

A.R.'s persistent cough for more than 5 days in the absence of other symptoms including fever or myalgia is typical with AB.[3] Pneumonia must be ruled out; however, normal oxygen saturation and lack of focal signs on pulmonary physical examination makes this diagnosis less likely. Sputum production is common, although not present in all cases of AB. Symptoms can be present at night, contributing to A.R.'s symptoms of fatigue.

Microbiology

Case 67-1, Question 2: What are the most likely causes of A.R.'s AB?

The causative agent for AB is identified in a minority of cases; however, when pathogens are isolated, they are usually of viral etiology.[2,5–7] The most common viruses associated with AB include influenza, parainfluenza, respiratory syncytial virus (RSV), coronavirus, adenovirus, and rhinovirus. The bacterial pathogens associated with AB include *Bordetella pertussis, Mycoplasma pneumoniae,* and *Chlamydophila pneumoniae*. Bacterial infection causing AB should primarily be considered in patients with underlying COPD, mechanical ventilation (tracheobronchitis), or in cases of outbreaks and exposures (e.g., *Bordetella pertussis*).[2]

Sick contacts, duration of incubation (2–7 days for viruses vs weeks for atypical bacteria), and previous exposures should be considered when determining the etiologic agent responsible for AB. Specific symptoms reveal infection caused by specific pathogens, such as an inspiratory whoop and posttussive emesis (*B. pertussis*), pharyngitis and cough lasting longer than 4 weeks (*Mycoplasma pneumoniae*), hoarseness with low-grade fever (*Chlamydophila pneumoniae*), or cough with fever and myalgias (influenza).[2] Given A.R.'s lack of sick contacts with bacterial infections (his son's recent colds are most likely of viral etiology), time course of present illness, and absence of symptoms suggestive of influenza, a viral etiology (other than influenza) is most likely to be the cause of his symptoms.

Clinical Diagnosis and Treatment

Case 67-1, Question 3: Should A.R. be provided an antimicrobial agent for his AB?

Antibiotics have not been shown to substantially reduce the duration or severity of AB.[8] Thus, expert guidelines in the United States and abroad recommend against the routine use of antimicrobial agents for the treatment of AB in patients who are immunocompetent.[3,6,7,9] Despite these recommendations, antimicrobials are frequently prescribed.[10] Inappropriate use of antimicrobial therapy is a public health concern because it may lead to unnecessary adverse events and increased antimicrobial resistance.

One exception to avoidance of antimicrobial therapy in AB is if *Bordetella pertussis* infection (whooping cough) is suspected. In these cases, antibiotic therapy with a macrolide antibiotic is recommended, and patients should remain in isolation for the first 5 days of treatment to prevent disease transmission.[1,3] In A.R.'s case, no antimicrobial agent is warranted.

Case 67-1, Question 4: Should a sputum culture be obtained from A.R.? What other diagnostics should be considered?

Obtaining a sputum sample for culture to determine the presence of the causative agent or diagnostic screening for atypical pathogens is not routinely indicated for AB. The rationale is that most of the identified pathogens have no specific treatment (viral illnesses), and the isolated organisms often are not true pathogens. Diagnostic screening, however, should be performed during influenza season or during outbreaks of *B. pertussis* or other atypical pathogens for infection control purposes. The use of biomarkers, such as procalcitonin or C-reactive protein (CRP), for the diagnosis of bacterial infection, may decrease inappropriate antimicrobial use in AB, but their routine use is not recommended at this time.[3,11,12]

Case 67-1, Question 5: What symptom-guided therapies should be offered to A.R.?

Symptom-guided therapies include the use of inhaled β_2-agonists (albuterol) for shortness of breath, particularly in patients with underlying reactive airway disease; inhaled or systemic steroids for persistent cough; nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, or acetaminophen to alleviate myalgias or fever; or antihistamines (brompheniramine), antitussives (codeine, dextromethorphan, or benzonatate), or mucolytics (guaifenesin) for cough. These symptom-guided treatments, however, are not backed by strong evidence demonstrating a clear benefit in patients with AB.[1–3,13,14] As such, using each of these treatments should consider the balance between perceived benefit and risk of adverse events. Given A.R.'s troublesome cough that has kept him up at night, a trial of an antitussive such as dextromethorphan is a reasonable first option. NSAIDs should be avoided given his concurrent aspirin use and lack of clear indication. An inhaled β_2-agonist or steroid is also not necessary at this time.[12,15]

Case 67-1, Question 6: Should a chest radiograph be ordered for A.R.? What other illnesses may be considered as the cause of his symptoms?

It is important to distinguish AB from pneumonia with chest radiograph or other imaging tests in the presence of fever, tachycardia, and tachypnea; physical examination findings such as egophony or rales; hypoxemia; or mental status changes (especially in the elderly).[2,3] Clinical differentiation of AB from AECOPD, postnasal drip, gastroesophageal reflux disorder (GERD), and asthma must also be made (discussed separately in this chapter and in Chapter 23, Upper Gastrointestinal Disorders, and in Chapter 18, Asthma, respectively). In A.R.'s case, no signs of pneumonia are present on physical examination or on reviewing symptomatology; therefore, no chest radiograph is warranted. Frequent or persistent symptoms or risk factors for COPD would warrant an investigation for chronic bronchitis. Wheezing or frequent AB outbreaks and GERD symptoms would guide evaluations for asthma or gastrointestinal disorders, respectively.

Patient Education

Case 67-1, Question 7: What education would you provide to A.R. to dissuade his perceived need for an antibiotic?

An evaluation of A.R.'s expectations for therapy is important to alleviate his potential concerns about the physician's decision to not prescribe antimicrobials. Overuse of antibiotics in AB is often driven by prescribers' acquiescence to patient requests for antibacterial drug therapy. Communication is key with each patient to provide insight into the potential causative agents of AB, the natural course of the disease, the role of symptomatic relief, and reasons for avoiding prescriptions for antibiotics.

ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Definition, Incidence, and Epidemiology

According to the Global Initiative for Chronic Obstructive Lung Disease (GOLD), COPD is a persistent and progressive reduction in airflow that results from repeated exposure to noxious particles. The chronic inflammation in the lungs results in a narrowing of the small airways, destruction of alveoli, and loss of elastic recoil. Of note, COPD may or may not be accompanied by increased sputum production and chronic cough. This disease is also characterized by acute exacerbations (AECOPD), which is defined as a worsening of symptoms that is more severe than the typical day-to-day variations that patients experience during the stable phase of their disease. Acute exacerbations of COPD typically require a change in medication to relieve symptoms and improve outcomes.[16] Maintenance therapy for COPD (discussed separately in Chapter 19, Chronic Obstructive Pulmonary Disease) is often targeted to reduce the severity and frequency of AECOPD.

COPD is associated with high health care expenditures, decreased quality of life, significant morbidity, and high mortality around the world. The global prevalence and annual death rate of COPD have been estimated to be 11.7% and 3 million deaths, respectively. Although COPD is a chronic illness, acute exacerbations are responsible for most of the economic and societal burden. AECOPD is associated with a decrease in quality-of-life measurements and an increase in the rate of decline in lung function, particularly if not treated early.[16,17]

The primary precipitating factors for AECOPD are infection of the bronchial tree and air pollution.[16,18–20] As many as one-third of the cases of AECOPD do not have a cause identified.

Pathophysiology

Bacteria, viruses, and pollutants lead to inflammatory responses.[20] Airway inflammation, associated with increases in interleukin-8, tumor necrosis factor-α, and neutrophils, contributes to pulmonary remodeling, decreased ciliary clearance of mucus, worsening airflow obstruction, and the respiratory symptoms associated with AECOPD.

Viruses have been identified as the etiologic cause of AECOPD in up to one-third of the cases, whereas bacteria have been identified in up to one-half of cases.[20] The microorganisms most commonly associated with AECOPD include *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis*. In patients with GOLD 3 (severe) or GOLD 4 (very severe) COPD, *Pseudomonas aeruginosa* is more prevalent.[16] Many patients with COPD are also colonized with bacteria during the stable phase of their illness.[21] Evidence suggests that either an increased burden of the same colonizing microorganism(s) or acquisition of a new bacterial species may be associated with exacerbating COPD symptoms.[16,21] Decreases in adaptive immune responses occur as COPD disease progresses, making patients susceptible to more frequent exacerbations caused by bacterial pathogens. Additionally, pathogens associated with exacerbations tend to increase in virulence and antimicrobial resistance as the underlying disease progresses.[16,19,20,22] A possible mechanism for prolonged infection and colonization in patients with COPD is suggested by interactions between both viruses and bacteria altering immune response.[20]

Clinical Presentation and Diagnosis

Common features of AECOPD include the following: breathlessness, increased cough, increased sputum volume, and increased sputum purulence. In contrast to AB, purulent sputum in AECOPD is associated with an acute bacterial infection.[22] Less specific symptoms include insomnia, fatigue, tachycardia, tachypnea, and a decrease in exercise tolerance. Patients often report a decrease in ability to conduct activities of daily living.[16]

Diagnostic considerations in the evaluation of patients with AECOPD include pulse oximetry and arterial blood gases, electrocardiogram, and complete blood count including white blood cell (WBC) differential. Chest radiographs are helpful to rule out pneumonia, pneumothorax, or pleural effusion. An assessment of comorbidities, such as the presence of heart failure or lung diseases (eg, asthma or lung cancer), should be performed to aid in both prognosis and diagnosis.[16],[18] Collection of sputum samples for Gram stain and culture are not generally recommended, but it may be helpful if patients are failing initial therapies. There is growing evidence that the bacterial infection biomarkers procalcitonin and CRP are useful to curtail antibiotic prescribing in patients with AECOPD. Similarly, evidence suggests that patients with AECOPD who have lower blood eosinophil levels may not experience clinical benefit from glucocorticoid administration. However, more robust supportive data are needed before these blood tests can be routinely recommended in the management of patients with AECOPD.[16]

Overview of Treatment

Pharmacotherapy directed at AECOPD includes bronchodilators and supplemental oxygen, antimicrobial therapy to decrease the burden of microorganisms, and corticosteroids targeting the inflammatory response.[16],[18] Methylxanthines (aminophylline or theophylline) are rarely used owing to conflicting and limited evidence of efficacy and concerns about toxicity.[16] Nonpharmacologic AECOPD treatment considerations include decisions regarding the site of care and the level of respiratory support. These nondrug considerations are not discussed in detail in this chapter but are available in the GOLD guidelines.[16]

Disease Severity

CASE 67-2

Question 1: T.H. is an 81-year-old White female presenting to the emergency department (ED) because she "cannot catch my breath." At baseline she is on 4 L of oxygen continuously via nasal cannula. However, during the last week, she has experienced worsening dyspnea necessitating help with daily activities including bathing and feeding. Her daughter had contacted T.H.'s primary care physician who directed the patient to the ED when T.H. seemed "out of it" and was difficult to arouse. T.H.'s daughter indicates that T.H. has been "having a cold" with increased sputum that is more yellow than in the past with frequent coughing spells. Past medical history is significant for very severe COPD, atrial fibrillation, depression, obstructive sleep apnea, morbid obesity, and a left humerus fracture. No medication allergies are noted. Medications at home include aspirin 81 mg PO daily, citalopram 20 mg PO daily, diltiazem extended-release capsule 240 mg PO daily, salmeterol–fluticasone dry powdered inhaler 50/250 one puff twice daily, and albuterol inhaler four puffs every 6 hours as needed for shortness of breath. Social history is significant for a >80-pack-year history of cigarette smoking, but she quit 4 to 5 years ago. In the ED she was afebrile, heart rate was 96 beats/minute, respiratory rate was 23 breaths/minute, blood pressure was 135/75 mm Hg, and oxygen saturation was 60% on 4 L of oxygen. T.H. is alert and oriented. She appears to be in respiratory distress, and she is using accessory muscles for breathing. Initial physical examination was significant for distant breath sounds and decreased air movement bilaterally, a noted absence of lower extremity edema, and an irregularly irregular heartbeat. Laboratory findings are as follows:

Arterial blood gases: pH, 7.34, P_{CO_2}, 60 mm Hg, P_{O_2}, 72 mm Hg
WBC, 9.8 × 10^3/μL (neutrophils 71%)
Hemoglobin, 12 g/dL
Platelets, 319 × 10^3/μL
Sodium, 135 mmol/L
Potassium, 3.7 mmol/L
Chloride, 91 mmol/L
Bicarbonate, 39 mmol/L
Blood urea nitrogen (BUN), 15 mg/dL
Serum creatinine (SCr), 1.21 mg/dL
Glucose, 104 mg/dL
Brain natriuretic peptide, 66 pg/mL
Troponin, >0.07 ng/mL
Thyrotropin, 1.63 μIU/mL

Chest radiograph indicated small pleural effusions, but it was otherwise negative for infiltrates or consolidation. An electrocardiogram indicated the presence of atrial fibrillation. Pulmonary function tests (obtained 1 year ago) indicated an FEV_1 to forced vital capacity ratio of 0.39 and an FEV_1 of 37% predicted.

How would you stage the severity of this exacerbation for T.H.?

T.H. has several risk factors for a poor outcome, including the presence of atrial fibrillation and severe COPD defined by her high home oxygen requirement, chronic carbon dioxide retention (as evidenced by her elevated partial pressure of carbon dioxide [P_{CO_2}]), and low baseline FEV_1.[16]

Clinical signs and symptoms consistent with a severe exacerbation include the use of accessory respiratory muscles, paradoxical chest wall movements, worsening or new cyanosis, peripheral edema, hemodynamic compromise, signs of right heart failure, and alterations in mental status.[16],[18] T.H. has two of these factors: reduced alertness and use of accessory muscles.

Disease Prevention

Case 67-2, Question 2: Which therapies should T.H. receive to alleviate her shortness of breath?

Supplemental oxygen to alleviate hypoxemia is a foundation of treatment for AECOPD. Controlled provision of oxygen is crucial to provide an oxygen saturation of >90% or a Pa_{O_2} of >60 mm Hg. Hypoxia that is not easily reversible warrants further examination for venous thromboembolism, pneumonia, or other causes. A repeat arterial blood gas should be obtained within 1 hour of initiation of supplemental oxygen to assess for carbon dioxide retention or acidosis.

Short-acting bronchodilators should be initiated promptly in all patients with AECOPD. Inhaled β_2-agonists, such as albuterol, with or without an anticholinergic agent (ipratropium), are the preferred agents.[16] If the patient does not respond, a methylxanthine (theophylline or aminophylline) may be considered as second-line therapy. There is no role for long-acting bronchodilators in AECOPD at this time.

Case 67-2, Question 3: Does T.H. need to be treated with antimicrobial therapy?

The "cardinal" symptoms of AECOPD include increases in sputum purulence, sputum volume, and dyspnea.[23] The use of cardinal symptoms as a method of staging AECOPD severity and deciding on antibiotic initiation has been used in several prospective studies and is recommended in the GOLD guidelines.[16],[24]

Experts advocate for the use of antibiotics for AECOPD, particularly when two or three cardinal symptoms are present.[16],[18] Specifically, the GOLD guidelines recommend antibiotics for patients with three cardinal symptoms (increased dyspnea, increased sputum volume, and increased sputum purulence); two cardinal symptoms, if increased sputum purulence is one of the symptoms; with the need for mechanical ventilation for their AECOPD.[16]

T.H. is exhibiting all three of the cardinal symptoms and, therefore, she should receive antibiotics. Likely benefits would be enhanced treatment success, improvement in pulmonary function, prevention of relapse, decreased risk for rehospitalization, and reduction of the severity of her exacerbation.

Case 67-2, Question 4: Which antimicrobial agent should be selected for treating T.H.? What duration of treatment is recommended?

Given T.H.'s history, diminished mental status, and risk factors for poor outcomes, intravenous (IV) administration seems appropriate for the initial antibiotic administration. Potential risk factors for *P. aeruginosa* should be evaluated. If T.H. demonstrates risk factors for *P. aeruginosa*, an antipseudomonal β-lactam, such as cefepime, ceftazidime, or piperacillin/tazobactam, would be an appropriate initial agent. If no risk factors for *P. aeruginosa* exist, a β-lactam/β-lactamase inhibitor such as ampicillin/sulbactam, or a third-generation cephalosporin such as ceftriaxone should be selected. If necessary, a respiratory fluoroquinolone such as moxifloxacin or levofloxacin could be considered, but the risks of adverse reactions

to this class of antibiotic, especially in the elderly, should be weighed carefully. All these therapies are active against drug-resistant *Streptococcus pneumoniae* (DRSP). If T.H. improves on one of these parenteral agents and is ready for discharge, T.H. could transition to an oral agent, such as high-dose amoxicillin/clavulanate.

Another important consideration for initial selection of antimicrobials is an evaluation of antibiotic history. Alternative antimicrobials from another class should be considered if patients have been previously treated in the last 3 months.[16] Additionally, if no improvements in symptoms occur within 72 hours, consider obtaining a sputum sample for directed therapy.[16]

The optimal duration of antibiotic therapy for AECOPD remains unknown. A duration of 5 to 10 days has been suggested, but this is an area in need of further research.[16]

Case 67-2, Question 5: Should T.H. be treated with corticosteroids? If so, which dose and duration is recommended?

In the setting of AECOPD, systemic corticosteroids help to improve lung function, shorten recovery time, and prevent relapses. Based on available evidence, the GOLD guidelines recommend a corticosteroid regimen of 40 mg/day of prednisone for 5 days in patients with AECOPD.[16] This regimen would be appropriate for T.H., although an equivalent intravenous regimen could be considered if she was not able to take an oral regimen. Higher doses and longer durations of therapy have not been found to confer a clinical advantage, and intravenous and oral regimens are considered equally effective.[25],[26] In those patients having received more than 3 weeks of steroids or multiple course of steroids in the previous months, tapering the dose should be considered. Although it is more expensive, nebulized budesonide is an alternative to oral corticosteroids for treatment of AECOPD.[16]

Enhancing Patient Outcomes

Case 67-2, Question 6: What factors should be assessed for T.H. during her hospitalization, and what follow-up should be planned to help assure she recovers fully and is not readmitted for COPD?

Hospitalized patients with AECOPD should both be optimally treated and their COPD management be assessed to decrease the likelihood of readmission. T.H.'s baseline COPD medications should be examined and adjusted based on disease severity (see Chapter 19, Chronic Obstructive Pulmonary Disease for details). Additionally, an assessment of her understanding of the role of medications (maintenance therapy vs rescue medications), ability to use inhalers correctly, access to her prescribed medications, and discussions regarding pulmonary rehabilitation should take place.[16,17] Consideration for pharmacologic venous thromboembolism prophylaxis (see Chapter 11, Thrombosis) should also be made in this high-risk population.[16,27]

PREVENTION OF COMMON RESPIRATORY INFECTIONS BY VACCINATION

Case 67-2, Question 7: Which vaccines should T.H. receive as part of her COPD management?

Vaccination records for influenza and *S. pneumoniae* should be evaluated in T.H. All patients with COPD should receive annual influenza vaccination to reduce the risk of serious illness, lower the frequency of AECOPD, and improve mortality.[16,17] Vaccination against *S. pneumoniae* with the 23-valent polysaccharide vaccine (PPSV23) is recommended for patients with COPD age 19 years and older, whereas vaccination with both the 13-valent conjugated pneumococcal vaccine (PCV13) and PPSV23 is recommended for all patients ages 65 years and older. Unlike with the influenza vaccine, however, there is no strong evidence for reduced AECOPD

risk with vaccination against *S. pneumoniae*. Despite this shortcoming, the guidelines recommend the pneumococcal vaccine as part of the overall health plan of the patient.

COMMUNITY-ACQUIRED PNEUMONIA

Definition, Incidence, and Epidemiology

Pneumonia is an infection of the lung parenchyma. Community-acquired pneumonia (CAP) refers to pneumonia acquired in the absence of health care system exposure (ie, hospital, long-term care, chronic antibiotic exposure). Diagnosis is dependent on clinical features and radiologic evidence of an infiltrate, and it is further supported by physical examination and/or hypoxemia.

Pneumonia accounts for ~3 million deaths per year worldwide and is leading in infectious causes of death.[28] Current estimates show that CAP accounts for 24.8 cases per 10,000 discharges in the U.S. adult population, and it affects primarily the elderly (65 to 79 years: incidence 63/10,000; 80 years and older: incidence 164.3/10,000).[29] In the pediatric population, CAP accounts for 15.7 cases per 10,000 discharges, with infants and young children showing increased risk (<2 years: incidence 62.2/10,000).[30] The overall mortality rate for patients 65 years and older is 5.6% and is more pronounced in hospitalized patients (8.5%) compared to outpatients (3.8%).[31]

Pathophysiology

Development of CAP occurs through the inhalation of infectious particles via droplets or aerosols, or the aspiration of oral flora. Rarely, hematogenous spread of bacteria from distant sources into the lungs may occur, as well as direct extension of infection to the lung from contiguous areas, such as the pleural or subdiaphragmatic spaces.

Once bacteria reach the tracheobronchial tree, defects in local pulmonary defenses facilitate infection. Contributing factors include inflammation-mediated injury to bronchial epithelium leading to depressed mucociliary clearance and a blunted cellular and humoral response. Patients with underlying or acquired immunodeficiencies are at an increased risk.

Clinical Presentation and Diagnosis

In the majority of CAP cases, patients present acutely with high fever, chills, tachypnea, tachycardia, and productive cough. Physical examination findings are usually localized to a specific lung zone and can include crackles, rhonchi, bronchial breath sounds, dullness, or egophony. On rare occasions, CAP exhibits a subacute presentation with fever, nonproductive cough, constitutional symptoms, and absent or diffuse findings on lung examination. Children with CAP may present with vomiting.

A chest radiograph or other imaging technique revealing an infiltrate is required for the diagnosis of CAP.[32] Radiographic manifestations of diseases such as congestive heart failure and malignancy can obscure the infiltrate, reinforcing the need to utilize both clinical and chest radiographic findings.

Based on updated recommendations from the most recent American Thoracic Society (ATS) and Infectious Disease Society of America (IDSA) guideline, pretreatment blood cultures and expectorated sputum cultures should only be obtained in patients presenting with severe CAP or in patients being empirically treated for suspicion of pneumonia because of methicillin-resistant *Staphylococcus aureus* (MRSA) or *P. aeruginosa*.[33]

Overview of Drug Therapy

Antibiotic therapy for CAP is empirical in the majority of cases and should always consider the most likely pathogen(s), underlying patient characteristics, and the severity of disease. Based on these

variables, clinicians can triage patients for risk of infection caused by antibiotic-resistant pathogens and appropriately tailor therapy.

CLINICAL PRESENTATION

CASE 67-3

QUESTION 1: J.T. is a 45-year-old female presenting to the ED with fevers, chills, and chest pain. Her symptoms have persisted for 4 days, and she has a productive cough with rust-colored sputum and dyspnea on exertion. She has had no recent illnesses and no known sick contacts, but she was recently released from a 2-year period of incarceration. She has tried acetaminophen to alleviate her fever and chest pain. Past medical history is positive for asthma, for which she is prescribed fluticasone and albuterol, and depression, for which she takes paroxetine. Vital signs reveal a temperature of 104.18 °F (40.1 °C), heart rate of 128 beats/minute, blood pressure of 130/76 mm Hg, and respiratory rate of 32 breaths/minute with accompanying oxygen saturation of 85% on 5 L of oxygen by nasal cannula. The remainder of the physical examination is notable for orientation to person but not place or time and for diffuse crackles bilaterally, which are most apparent on the right side. Laboratory results include the following:

WBC count, 15,500 cells/μL
Hematocrit, 29.3%
Platelets, 150,000 cells/μL
Sodium, 133 mmol/L
Potassium, 3.8 mmol/L
BUN, 23 mg/dL
SCr, 0.8 mg/dL
HCO_3, 28 mEq/L
Glucose 148, mg/dL
Arterial blood gases: pH 7.42, P_{O_2}, 61 mm Hg, P_{CO_2}, 46 mm Hg

A test for human immunodeficiency virus is negative. Chest radiograph reveals a right lower lobe infiltrate. Upon interview, J.T. reveals an allergy to penicillin that she states led to a rash following exposure about 15 years ago.

What signs, symptoms, and tests are consistent with CAP in J.T.?

Most patients with CAP present with cough with sputum production, dyspnea, and pleuritic chest pain.[34] Patients may show signs of the systemic inflammatory response syndrome, including tachycardia, tachypnea, fever, and an abnormal WBC count.[35]

Auscultatory examination often reveals decreased breath sounds, crackles or rhonchi, or egophony in patients with consolidation. Signs and symptoms associated with severe pneumonia are grouped into minor and major criteria as defined by the ATS/IDSA guidelines.[32,33] Minor criteria include respiratory rate >30 breaths/minute at admission; ratios of the Pa_{O_2} to fraction of inspired oxygen (F_{IO_2}), (Pa_{O_2}/F_{IO_2}), <250 mm Hg; systolic blood pressure (SBP) <90 mm Hg, or diastolic blood pressure (DBP) <60 mm Hg; confusion; multilobar infiltrates; SBP <90 mm Hg, despite aggressive fluid resuscitation; BUN of at least 20 mg/day; leukopenia; thrombocytopenia; and hypothermia. Major criteria include requirement of mechanical ventilation and requirement of vasopressors for more than 4 hours.

Clinical findings and a positive infiltrate by chest radiograph or other imaging technique is required for the diagnosis of pneumonia.[32] Patients who are hospitalized based on clinical symptoms absent of positive imaging should have repeat imaging performed 24 to 48 hours postadmission.

Disease Severity

Case 67-3, Question 2: Given the clinical condition of J.T. in the ED, where should her care be continued?

The first decision after a diagnosis of CAP is to determine whether the patient requires hospitalization. Several predictive rules facilitate site-of-care decision-making. The two best-studied tools that are endorsed by the ATS/IDSA guidelines are the pneumonia severity index (PSI) and the CURB-65 rule, with preference given to PSI.[33]

The PSI uses individually scored demographic characteristics (age, gender, nursing home residence), comorbidities (liver disease, CHF, renal disease, neoplasm), physical examination findings (mental status, RR, SBP, temp, HR), and laboratory data (sodium, glucose, Hct, BUN). The total PSI score categorizes patients into

one of five classes that are associated with an escalating risk of death (**Table 67-1**).[36]

Table 67-1
Predicted Pneumonia Mortality and Recommended Site of Care

System and Score	Predicted 30-Day Mortality (%)	Recommended Site of Care
PSI strata I–II (≤70)	0.1–0.7	Outpatient
PSI strata III (71–90)	0.9–2.8	Admit to hospital ward
PSI strata IV–V (≥91)	9.3–27	Admit to hospital; consider ICU
CURB-65 score 0–1	0.7–2.1	Outpatient
CURB-65 score 2	9.2	Admit to hospital ward
CURB-65 score ≥3	14.5–57	Admit to ICU

CURB-65, confusion, uremia, increased respiratory rate, low blood pressure, and age ≥65 years; ICU, intensive care unit; PSI, pneumonia severity index.

Source: Fine MJ, Auble TE, Yealy DM, et al. A prediction rule to identify low-risk patients with community-acquired pneumonia. *N Engl J Med*. 1997;336:243–250.

The CURB-65, developed by the British Thoracic Society, is a simple tool that focuses on five assessments: confusion (owing to pneumonia), uremia (BUN > 19 mg/dL), respiratory rate of at least 30 breaths/minute, SBP <90 mm Hg systolic or DBP <60 mm Hg, and age of at least 65 years.[37] Each criteria receives one point, and the cumulative score is associated with a specific (rising with higher score) 30-day mortality risk. Based on the score, subsequent care should be as follows: 0–1 = outpatient; 2 = admission to ward; ≥3 = intensive care unit (ICU) care.

Both scales identify patients at low risk of death, but the PSI was found to have a higher sensitivity and negative predictive value for identifying mortality.[37] The need for ICU admission can be subjective; however, the ATS/IDSA guidelines recommend that patients with three or more minor criteria, or at least one major criteria for severe CAP, be admitted to the ICU.[33]

Using the PSI, patient J.T.'s CAP severity can be assessed as: 45-year-old female (35 points [45 for age − 10 for gender female]); respiratory rate >30 breaths/minute (20 points); heart rate >125 beats/minute (20 points); temperature >40 °C (15 points); hematocrit <30% (10 points); and altered mental status (20 points). A total score of 120 points places J.T. in risk strata IV (30-day mortality risk: 9.3%–27%), and she should be admitted to the hospital, potentially to the ICU.

Using the CURB-65, J.T. has a score of 3 (30-day mortality of 9.2%) based on uremia, confusion, and increased respiratory rate, and she should be admitted to the ICU.

Case 67-3, Question 3: What testing should be performed to obtain a microbiologic diagnosis in J.T.?

J.T. has no major criteria for severe sepsis, but at least three minor criteria, qualifying her to have severe CAP (BUN >20 [23], RR >30 [32], confusion [A & O × 1]). Based on this, J.T. should get both blood and expectorated sputum cultures collected before treatment initiation.

Microbiologic testing is not routinely recommended for patients in either the outpatient or inpatient setting unless they are diagnosed with severe CAP or suspected of being infected with MRSA or *Pseudomonas*.[33] Urine antigen tests for pneumococcus and *Legionella pneumophila* serogroup 1 are only indicated in severe CAP or in cases where epidemiologic factors warrant testing (eg, travel or exposure to an outbreak). Because of conflicting evidence, procalcitonin levels are not currently recommended as a means to determine the utility of antibiotic therapy.

Current guidelines recommend influenza testing during traditional "flu season" utilizing a rapid influenza molecular assay.[33]

Microbiology

Case 67-3, Question 4: What pathogens are most likely in J.T.?

Pathogens are only identified in 38% of CAP, with bacterial causes identified in only 14% of patients.[29] The top three pathogens responsible for CAP are rhinovirus, influenza, and *S. pneumoniae.* The major pathogens for CAP are summarized in **Table 67-2**. *Streptococcus pneumoniae* uses two survival strategies.[38] The first pertains to a noninvasive phenotype that uses surface adhesions, immune evasion strategies, and secretory defenses to promote long-term carriage within the nasopharynx. Deficits in host defense, such as an immunocompromised state, allow colonizing strains of low virulence to cause invasive disease. The second survival strategy depends on efficient person-to-person transmission and associated rapid disease induction by an invasive phenotype. Risk factors for the invasive pneumococcal phenotype are age younger than 2 years or older than 64 years, asplenia, alcoholism, diabetes mellitus, antecedent influenza, defects in humoral immunity, and human immunodeficiency virus infection.[39] Other risk factors less likely to be associated with invasive disease include poverty and crowding, cigarette smoking, chronic lung disease, severe liver disease, recent exposure to antibiotics, and chronic proton-pump inhibitor use.[39]

Table 67-2
Common Pathogens in Community-Acquired Pneumonia

Ambulatory	Hospitalized, Non-ICU	Hospitalized, ICU
Streptococcus pneumoniae	*S. pneumoniae*	*S. pneumoniae*
Mycoplasma pneumoniae	*M. pneumoniae*	*Staphylococcus aureus*
Haemophilus influenzae	*C. pneumoniae*	*Legionella* species
Chlamydophila pneumoniae	*Staphylococcus aureus*	Gram-negative bacilli
Respiratory viruses[a]	*H. influenzae*	*H. influenzae*
	Legionella species	
	Respiratory viruses[a]	

[a]Influenza A and B, adenovirus, respiratory syncytial virus, and parainfluenza.

Source: Metlay JP, Waterer GW, Long AC, et al. Diagnosis and treatment of adults with community-acquired pneumonia: an official clinical practice guideline of the American Thoracic Society and Infectious Disease Society of America. *Am J Respir Crit Care Med*. 2019;200:e45–e67.

Following the introduction of the first pneumococcal conjugate vaccine (PCV7) in 2000 and the expanded PCV13 in 2010, the incidence of invasive disease and all-cause pneumonia have significantly fallen.[40] However, the advent of these vaccines has not led to a significant pneumonia decline in high-risk pediatric patients, specifically children younger than 5 years with moderate-to-severe asthma, or in adults with asthma and one or more of the following comorbid conditions: heart disease, lung disease, diabetes, or neuromuscular disease.[40] Current Centers for Disease Control and Prevention (CDC) guidelines recommend PCV13 for patients younger than age 2 years or patients ages 2 to 64 years who are high risk for pneumococcal disease and the pneumococcal polysaccharide vaccine (PPSV23) for high-risk populations and all patients 65 years and older.[40]

Atypical pathogens, including *L. pneumophila*, *C. pneumoniae*, and *M. pneumoniae*, account for ~25% of CAP worldwide.[41] However, atypical pathogens may be present in up to 60% of CAP episodes because of coinfection.[42] Polymicrobial infection including atypical pathogens may lead to a more complicated course with extended lengths of hospital stay. Several studies have shown that antibiotic regimens that include coverage against these pathogens demonstrate a survival benefit over regimens that do not.[43–46] Legionnaires' disease, caused primarily by *L. pneumophila* serogroup 1, accounts for 2% to 7% of CAP and is considered more severe among hospitalized patients.[41] Patients may present with high fever, nonproductive cough, low serum sodium concentration, high concentration of lactate dehydrogenase, and low platelet counts.[47]

Epidemiologic factors may favor the presence of certain bacterial pathogens and are listed in **Table 67-3**.[32] This highlights the importance of performing a thorough patient history to assist in the direction of therapy. Additional factors such as chronic oral steroid

use (≥10 mg prednisone/day), immunosuppression, and frequent antibiotic therapy will require augmented therapy.[48]

Table 67-3

Community-Acquired Pneumonia: Underlying Conditions and Commonly Encountered Pathogens

Condition	Commonly Encountered Pathogen(s)
Alcoholism	Oral anaerobes, *Klebsiella pneumoniae*, *Acinetobacter* spp., *Mycobacterium tuberculosis*
COPD or smoking	*Pseudomonas aeruginosa*, *Legionella* spp.
Aspiration	Gram-negative enteric pathogens, oral anaerobes
Lung abscess	CA-MRSA, oral anaerobes, endemic fungal pneumonia, *M. tuberculosis*, atypical mycobacteria
Exposure to bat or bird droppings	*Histoplasma capsulatum*
Exposure to birds	*Chlamydophila psittaci* (if poultry: avian influenza)
Exposure to rabbits	*Francisella tularensis*
Exposure to farm animals or parturient cats	*Coxiella burnetii* (Q fever)
HIV infection (early)	*M. tuberculosis*
HIV infection (late)	*M. tuberculosis*, *Pneumocystis jirovecii*, *Cryptococcus* spp., *Histoplasma* spp., *Aspergillus* spp., atypical mycobacteria (especially *Mycobacterium kansasii*), *Pseudomonas aeruginosa*
Hotel or cruise ship stay in previous 2 weeks	*Legionella* spp.
Travel to or residence in southwestern United States	*Coccidioides* spp., hantavirus

Travel to or residence in Southeast and East Asia	*Burkholderia pseudomallei*, avian influenza, SARS
Cough >2 weeks with whoop or posttussive vomiting	*Bordetella pertussis*
Structural lung disease (eg, bronchiectasis)	*P. aeruginosa*, *Burkholderia cepacia*, *Staphylococcus aureus*
Injection drug use	*S. aureus*, anaerobes, *M. tuberculosis*
Endobronchial obstruction	Anaerobes, *S. aureus*
In context of bioterrorism	*Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), *F. tularensis* (tularemia)

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus; SARS, severe acute respiratory syndrome.

Source: Adapted from Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007;44(suppl 2):S27–S72. Reproduced by permission of Infectious Diseases Society of America.

Staphylococcus aureus is a major cause of nosocomial pneumonia; however, its significance in CAP is less clear. Traditionally, *S. aureus* has not been considered a common cause of CAP (~2.5% of cases), but it most likely occurs in association with influenza or in patients with lung abscess.[32],[49] Community-associated MRSA (CA-MRSA) is significantly different from the typical hospital-acquired strain. These differences include susceptibility to non–β-lactam antibiotics (eg, clindamycin and doxycycline) and clinical syndrome (necrotizing radiographic presentation, empyema formation, hemoptysis, and profound hypoxemia) associated with toxins including Panton–Valentine leukocidin.[50] Toxin-producing strains are also part of methicillin-sensitive *S. aureus*'s (MSSA) virulence.[51] The outcomes of patients

with MRSA and MSSA CAP are similarly poor, with prolonged length of hospital stay and a nearly 25% mortality.[52]

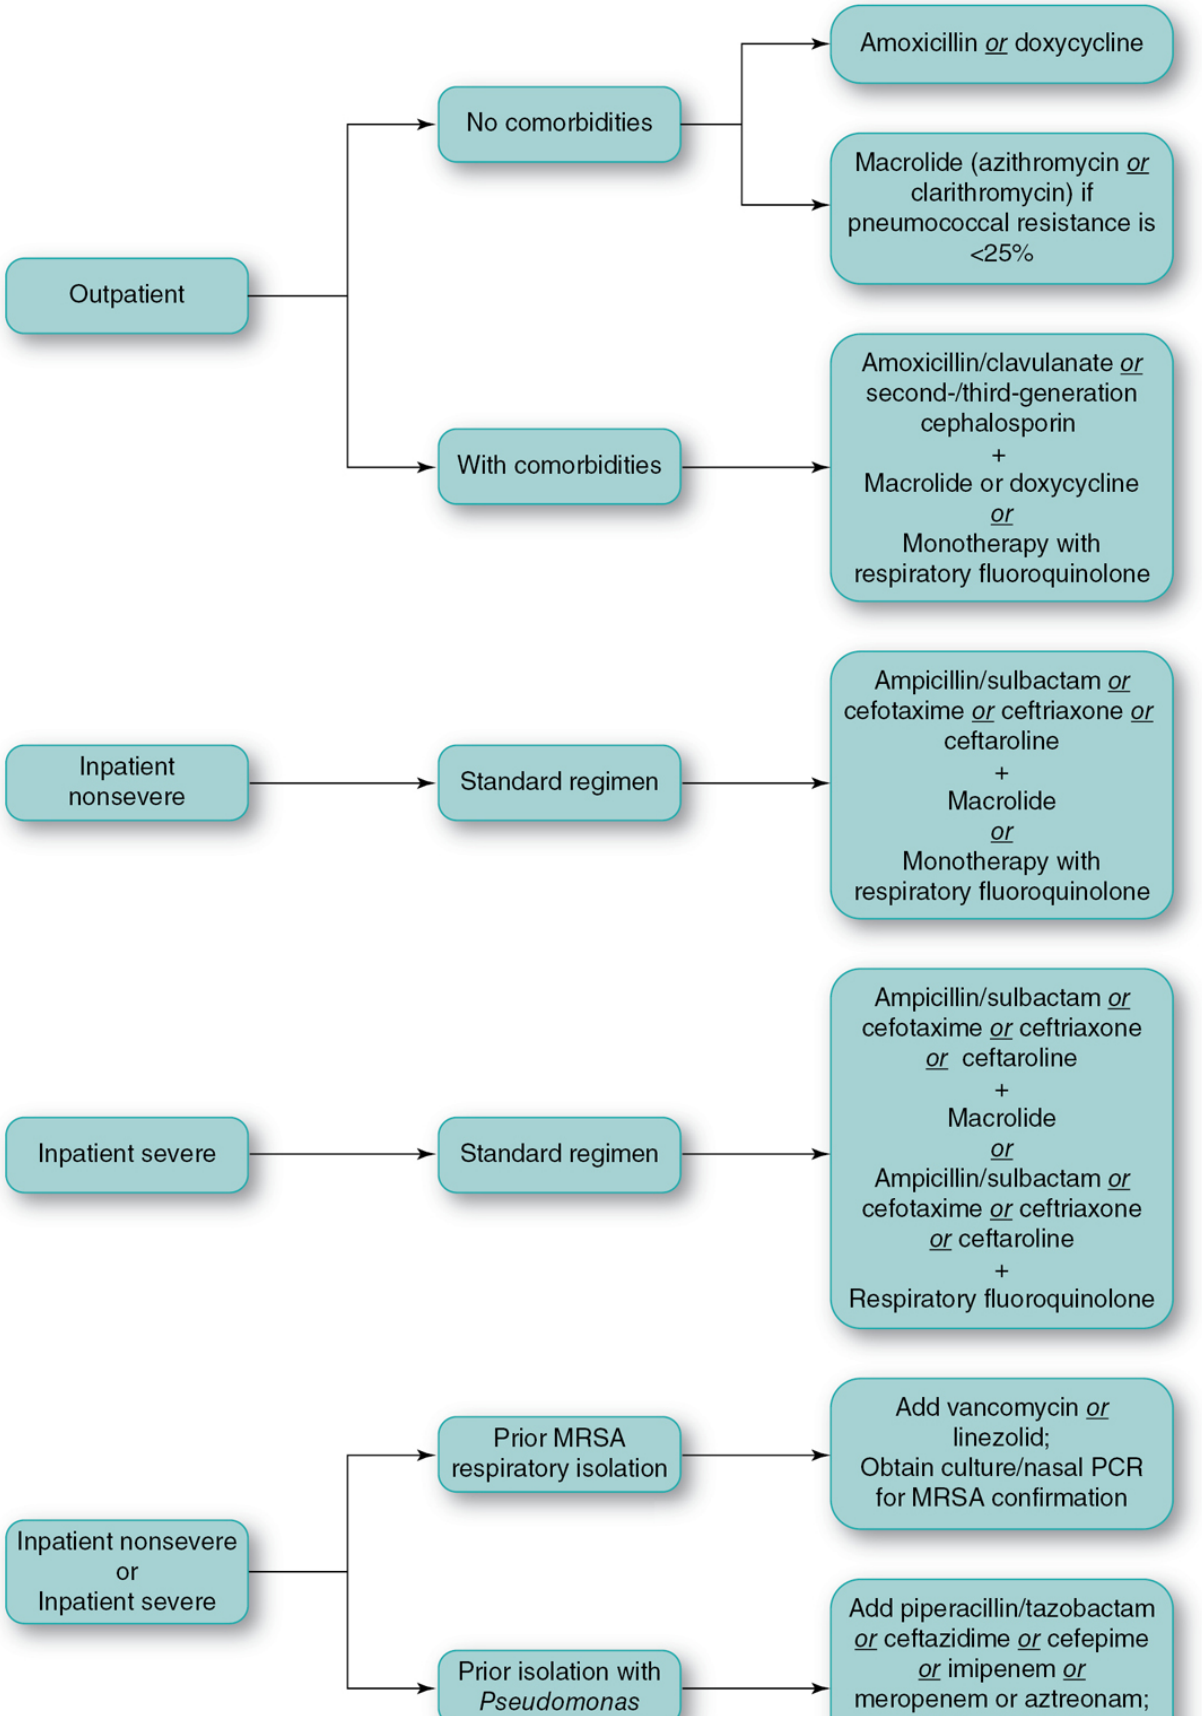
Respiratory virus can be the primary cause of CAP (22% in the United States) and may predispose patients to infection by another pathogen, often bacterial.[53] Respiratory viruses that cause CAP include influenza A and B, respiratory syncytial virus, rhinovirus, parainfluenza, adenovirus, human metapneumovirus, and coronavirus.[54] In patients coinfected with both viral and bacterial pathogens, the most common bacteria are *S. pneumoniae*, *S. aureus*, and atypicals.

Possible microbes causing J.T.'s CAP include *S. pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, *S. aureus*, *H. influenzae*, *Legionella* species, and respiratory viruses.

Antibiotic Therapy

Case 67-3, Question 5: Which antimicrobial agent(s) should be chosen for the initial management of J.T.?

An approach to the patient with CAP and recommended antibiotic regimens based on the patient's site of care and severity of illness is provided in **Figure 67-1**. Delayed antibiotic therapy has been associated with an increased length of hospital stay and decreased survival in CAP; therefore, a rapid and correct diagnosis is imperative.[55],[56] ATS/IDSA CAP treatment guidelines recommend the first dose of antibiotic be given in the ED in an effort to avoid treatment delays associated with the hospital admission process.[33]



Outpatient
No comorbidities
Amoxicillin or doxycycline
Macrolide (azithromycin or clarithromycin) if pneumococcal resistance is <25%
With comorbidities
Amoxicillin/clavulanate or second-/third-generation cephalosporin + Macrolide or doxycycline or Monotherapy with respiratory fluoroquinolone
Inpatient nonsevere
Standard regimen
Ampicillin/sulbactam or cefotaxime or ceftriaxone or ceftaroline + Macrolide or Monotherapy with respiratory fluoroquinolone
Inpatient severe
Standard regimen
Ampicillin/sulbactam or cefotaxime or ceftriaxone or ceftaroline + Macrolide or Ampicillin/sulbactam or cefotaxime or ceftriaxone or ceftaroline + Respiratory fluoroquinolone
Inpatient nonsevere or Inpatient severe
Prior MRSA respiratory isolation
Add vancomycin or linezolid; Obtain culture/nasal PCR for MRSA confirmation
Prior isolation with Pseudomonas
Add piperacillin/tazobactam or ceftazidime or cefepime or imipenem or meropenem or aztreonam;

Figure 67-1 Approach to empiric antibiotic therapy in patients with community-acquired pneumonia. MRSA, methicillin-resistant *Staphylococcus aureus*; PCR, polymerase chain reaction. (From Metlay JP, Waterer GW, Long AC, et al. Diagnosis and treatment of adults with community-acquired pneumonia: an official clinical practice guideline of the American Thoracic Society and Infectious Disease Society of America. *Am J Respir Crit Care Med*. 2019;200:e45–e67.)

All adult patients, regardless of treatment setting, require at least empiric treatment for pneumococcus and atypical pathogens.[33] The choice of the initial regimen should be based on medical comorbidities or epidemiologic factors, including the possibility of antibiotic-resistant causative organisms. Pediatric patients should be treated with ampicillin or amoxicillin if younger than 5 years old, with a macrolide added for atypical coverage for children five years and older.[57] Children who are unvaccinated or have risk factors for DRSP should receive ceftriaxone in place of ampicillin or amoxicillin. Factors that increase the risk of DRSP are located in **Table 67-4**.

Table 67-4
Risk Factors for β-Lactam–Resistant *Streptococcus pneumoniae*

Age >2 or >65 years
β-Lactam therapy within the previous 3 months
Alcoholism
Medical comorbidities
Immunosuppressive illness or therapy
Exposure to a child in a day-care center
Recent hospitalization

Source: Mandell LA, Wunderink RG, Anzueto A, et al. Infectious Diseases Society of America/American Thoracic Society consensus guidelines on the management

of community-acquired pneumonia in adults. *Clin Infect Dis*. 2007;44(suppl 2):S27–S72.

For patients without comorbidities, the preferred treatment in the outpatient setting is high-dose amoxicillin (1 g PO tid) or doxycycline (100 mg PO bid). Macrolide antibiotics (azithromycin 500 mg PO day 1, 250 mg PO days 2 to 5; clarithromycin 500 mg PO bid or 1 g ER PO daily) are recommended only when local pneumococcal isolates exhibit <25% resistance.[33] Adults with comorbidities should be treated with a combination of β-lactam plus macrolide or doxycycline, or with respiratory fluoroquinolone monotherapy (levofloxacin, moxifloxacin, or gemifloxacin). Amoxicillin/clavulanate is often the preferred β-lactam of choice. Amoxicillin (90 mg/kg/day) is the preferred outpatient treatment in children.[57]

β-Lactam resistance occurs through alteration of one or more of the penicillin-binding proteins that mediate bacterial cell wall production.[58] Penicillin-binding protein alterations in resistant strains decrease the affinity to all β-lactams such that higher concentrations are required for binding and inhibition of the enzyme. This further justifies the need for appropriate dosing of β-lactams in the treatment of CAP to minimize the development of resistance and promote optimal clinical outcomes.[59]

Adults with nonsevere CAP requiring inpatient admission, but without previous risk factors for or respiratory isolation of MRSA or *P. aeruginosa,* should be treated with a combination β-lactam (ampicillin/sulbactam, cefotaxime, ceftriaxone, or ceftaroline) plus a macrolide, or with a respiratory fluoroquinolone monotherapy.[33] Patients with no previous respiratory isolates, but with risk factors for MRSA or *P. aeruginosa,* should have cultures obtained, but should hold off any additional therapies until positive results are reported. Adults with severe CAP requiring inpatient admission without previous respiratory isolation of or risk factors for MRSA or *P. aeruginosa* can be treated with either a β-lactam plus a macrolide or a β-lactam plus a respiratory fluoroquinolone. Patients with severe disease and risk factors for MRSA, or any patient with a previous respiratory isolate of MRSA, should have either vancomycin (15

mg/kg IV q12h; dosing adjusted based on serum levels and renal function) or linezolid (600 mg IV q12h) added to the standard regimen. Sputum cultures and a nasal polymerase chain reaction (PCR) should be ordered to guide the remainder of therapy.[33] Patients with severe disease and risk factors for *P. aeruginosa,* or any patient with a prior respiratory isolation of *P. aeruginosa,* should have an antipseudomonal antibiotic (piperacillin/tazobactam 4.5 g IV q6h, cefepime 2 g IV q8h, ceftazidime 2 g IV q8h, imipenem 500 mg IV q6h, meropenem 1 g IV q8h, or aztreonam 2 g IV q8h; dosing adjusted on renal function) added to the standard regimen. Sputum cultures should be ordered to guide the remainder of therapy.

Children requiring hospitalization for CAP who are up-to-date with vaccinations should be treated with intravenous ampicillin monotherapy if they are younger than age 5 years, with azithromycin added for patients 5 and older. Patients who are unvaccinated should receive ceftriaxone in place of ampicillin because of both pneumococcal and *Haemophilus* concerns.[57]

For patients with contraindications to macrolides or fluoroquinolones, doxycycline may be added to β-lactam treatments. This is most commonly because of cardiac abnormalities, as both classes of medications can prolong the QTc interval. In patients with severe allergic reactions to β-lactams, fluoroquinolones are the preferred agents. Fluoroquinolones are often avoided as first-line therapy because of increasing concerns of resistance mediated by mutations in the DNA gyrase gene *gyrA* and the topoisomerase IV genes *parC* and *parE*, as well as efflux pump–mediated means.[60] Resistance is primarily the result of overuse in clinically nonrelevant situations. This is a common target of institutional antimicrobial stewardship programs. ATS/IDSA guideline-concordant therapy for hospitalized patients has been associated with improved patient outcomes including decreases in time to achieve clinical stability, total duration of parenteral therapy, and hospital length of stay, as well as improved in-hospital survival.[61],[62]

J.T.’s qualifies for severe CAP based on her three minor criteria noted before. Treatment should be started in the ED after obtaining a respiratory specimen and pretreatment blood cultures for Gram stain

and culture. As far as we know, J.T. does not possess risk factors for specific bacteria, such as MRSA or *P. aeruginosa*, but she does have a noted allergy to penicillin that resulted in a rash. This allergy should not necessitate deviation from guideline-directed therapy given the length of time since the allergy was noted (15 years ago) and the low likelihood of cross-sensitivity between β-lactams. J.T. should receive a β-lactam (ceftriaxone) plus a macrolide (azithromycin) or a respiratory fluoroquinolone (levofloxacin) intravenously for empiric treatment. J.T.'s recent incarceration is a risk factor for CA-MRSA infection but more information regarding where she was jailed would be needed to make a definitive decision on adding MRSA coverage to her regimen. J.T. should at the very least have a nasal PCR swab performed to determine MRSA colonization, which could augment the direction of her treatment.

Case 67-3, Question 6: What is the appropriate length of therapy for J.T.?

Although some recent evidence has suggested that shorter courses of therapy (5–7 days) are equally efficacious to extended durations (10–14 days), the 2019 ATS/IDSA guidelines recommend that treatment duration be guided by clinical improvement: normalization of vital signs including oxygen saturation, ability to eat, and resolution of any cognitive dysfunction.[33] Treatment should be no <5 days, and it is understood that some patients may require longer courses of antibiotics based on their underlying health prior to admission and how quickly clinical improvement begins. Patients should be afebrile for at least 48 to 72 hours before therapy is discontinued. Follow-up chest radiographs are no longer indicated if a patient achieves clinical stability within 5 to 7 days.

CASE 67-4

Question 1: F.E. is a 56-year-old male presenting to the ED with fever, chills, nausea, and vomiting for the last 7 days, and more recently, shortness of breath with productive cough with white sputum for the past 4 days. He visited his family ~2 days prior to symptoms, where two of his relatives were thought to

have an unconfirmed viral illness. Initial assessment reveals the patient to be alert and oriented times three, but falling asleep during assessment, pulses present with brisk capillary refill, decreased lung sounds bilaterally, and no peripheral edema. Past medical history is significant for hypertension and diabetes mellitus. The patient has no known drug allergies. Medications at home include aspirin 81 mg PO daily, hydrochlorothiazide 25 mg PO daily, lisinopril 20 mg PO daily, and atorvastatin 40 mg PO daily. Social history is significant for smoking one pack of cigarettes per week.

In the ED, he had a temperature of 102.02 °F (38.9 °C), heart rate of 112 beats/minute, respiratory rate of 22 breaths/minute, SBP/DBP of 126/80 mm Hg, and oxygen saturation of 93% on 2 L of oxygen via nasal cannula. Laboratory results include the following:

WBC count, 2900 cells/μL
Hematocrit, 47.1%
Platelets, 129,000 cells/μL
Sodium, 127 mmol/L
Potassium, 4.6 mmol/L
BUN, 7 mg/dL
SCr, 0.73 mg/dL
Glucose, 117 mg/dL

Chest radiograph showed bilateral interstitial infiltrates; real-time (RT)–PCR was positive for influenza A.

What is the most likely reason for F.E.'s influenza infection?

Influenza viruses spread when a person who is infected coughs or sneezes near a susceptible person.[63] The usual incubation period for influenza is 1 to 4 days, and the time between onset among patients who have come into contact with one another is likely to be 3 to 4 days.[64] Adults can shed influenza virus from the day before symptoms begin through 5 to 10 days after illness onset.[65] Young children shed virus several days before illness onset, and they can be infectious for 10 days or more after onset of symptoms. Prolonged viral replication can occur in adults with severe disease, including those with comorbidities or those receiving corticosteroid therapy.[66,67] Severely immunocompromised persons can shed virus for weeks to months.[68,69]

Case 67-4, Question 2: Should F.E. be treated with antiviral agents?

Patients with laboratory-confirmed or suspected influenza virus meeting the following criteria should be treated with antiviral therapy within 48 hours of symptom onset: persons of any age hospitalized because of respiratory illness; outpatients of any age with severe or progressive illness; those at high-risk for complications from influenza infection (**Table 67-5**); children younger than age 2 years and adults ages 65 years and older; and pregnant females and those within 2 weeks postpartum.[70] Nonimproving high-risk patients or those with symptoms >48 hours and requiring hospitalization should also be considered for antiviral treatment. F.E. falls into the latter category and should be treated for influenza A. Antibiotic treatment is recommended for hospitalized patients with CAP, even if influenza is suspected, and therapy should be directed at likely bacterial pathogens based on the patient's disease severity, previous respiratory isolates, and known risk factors.[33]

Table 67-5

Patients at High Risk of Complications From Influenza

Unvaccinated infants ages 12–24 months
Persons with asthma or other chronic pulmonary diseases (eg, COPD, cystic fibrosis)
Persons with hemodynamically significant cardiac disease
Persons with immunosuppressive disorders or who are receiving immunosuppressive therapy
Persons who are HIV-infected
Persons with sickle cell anemia and other hemoglobinopathies
Persons with diseases that require long-term, high-dose aspirin therapy, such as rheumatoid arthritis
Persons with chronic renal dysfunction
Persons with cancer
Persons with chronic metabolic disease, such as diabetes mellitus
Persons with central nervous system disorders that may compromise the handling of secretions such as neuromuscular disorders, cerebral vascular accidents, or seizure disorders
Adults ages ≥65 years

Residents of any age of nursing homes or other long-term care institutions

COPD, chronic obstructive pulmonary disease; HIV, human immunodeficiency virus.

Source: Uyeki TM, Bernstein HH, Bradley JS, et al. Clinical practice guidelines by the Infectious Diseases Society of America: 2018 update on diagnosis, treatment, chemoprophylaxis, and institutional outbreak management of seasonal influenza. *Clin Infect Dis*. 2019;6:895–902.

Antiviral Therapy

Case 67-4, Question 3: Which antiviral agent(s) should F.E. receive?

Influenza susceptibility profiles to antiviral agents evolve rapidly, and treating clinicians should be familiar with updated resistance data found at the CDC website: www.cdc.gov/flu. There are currently four Food and Drug Administration (FDA)-approved antiviral medications indicated for influenza treatment. Three of these drugs, all recommended by the 2018 IDSA guideline update, are neuraminidase inhibitors: oseltamivir, zanamivir, and peramivir.[70] The inhibition of neuraminidase prevents cleavage of sialic acid residues on the cell surface of the virus, thereby preventing the release of virus from infected cells. The fourth drug, baloxavir, was approved in October 2018, too late to be included in the most recent guideline update.[71] Baloxavir inhibits viral replication by inhibiting the endonuclease activity of the polymerase acidic protein, which is required for viral gene transcription. Information on the currently available influenza antiviral therapies is included in **Table 67-6**. Because of high rates of resistance, adamantines (amantadine and rimantadine) are no longer recommended for treatment of influenza. FE could be treated with any of the four available antiviral medications with oseltamivir administered by mouth bid for 5 days, zanamivir inhaled bid for 5 days, peramivir administered IV in a single dose, and baloxavir by mouth in a single dose.

Table 67-6

Comparison of Current Antiviral Treatment for Influenza

	Oseltamivir	Zanamivir	Peramivir	Baloxavir
Drug class	Neuraminidase inhibitor	Neuraminidase inhibitor	Neuraminidase inhibitor	Influenza cap-dependent endonuclease inhibitor
Route of administration	PO	Inhalation	IV	PO
FDA-approved treatment age	All ages	≥7 years	≥13 years	≥12 years
Treatment duration	bid for 5 days	bid for 5 days	Single dose over 15 minutes	Single dose
Side effects	Nausea, vomiting, abdominal pain	Nasal and throat discomfort, headache, bronchospasm	Diarrhea; serious skin reactions; sporadic, transient neuropsychiatric events	Diarrhea, bronchitis, rhinorrhea, headache, nausea

bid, two times a day; IV, intravenous; PO, by mouth.

Source: Uyeki TM, Bernstein HH, Bradley JS, et al. Clinical practice guidelines by the Infectious Diseases Society of America: 2018 update on diagnosis, treatment, chemoprophylaxis, and institutional outbreak management of seasonal influenza. *Clin Infect Dis*. 2019;6:895–902.

Antiviral therapies should be initiated as soon as possible after illness onset, ideally within 48 hours, as this is when the majority of viral replication occurs. However, treatment of any person with confirmed or suspected influenza requiring hospitalization is recommended for up to 96 hours postillness onset.[72],[73] For patients whose illness is prolonged, treatment regimens may need to be extended beyond 5 days.

Resistance to neuraminidase inhibitors oseltamivir and zanamivir has been identified during treatment of seasonal influenza, caused by a specific mutation leading to a histidine to tyrosine substitution (H275Y) in neuraminidase.[74],[75] Oseltamivir resistance, which can occur within one week of treatment initiation, was reported particularly among immunocompromised patients infected with the 2009 H1N1 virus.[76],[77]

HOSPITAL-ACQUIRED PNEUMONIA AND VENTILATOR-ASSOCIATED PNEUMONIA

Definitions and Incidence

Despite advances in therapy and prevention, hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP) are associated with significant morbidity and mortality. HAP is defined as pneumonia that occurs at least 48 hours after hospital admission. VAP refers to pneumonia that arises 48 to 72 hours after endotracheal intubation.[48]

Epidemiology

HAP is the second most common nosocomial infection in the United States, with urinary tract infections as the most common.[48] Based on a prospective cohort study, ~7% of ICU patients developed HAP and over 75% of them had VAP.[78] A retrospective cohort study of 4543 hospitalized patients with culture-positive pneumonia observed that HAP accounted for 18.4% and VAP for 11%. Mortality rates associated with HAP groups were comparable (19.8% and 18.8%, respectively) and were significantly lower than those for VAP (29.3%). Mean lengths of stay also differed between patients with HAP and VAP (15.2 ± 13.6 days, and 23 ± 20.2 days, respectively).[79]

The disease onset is an important epidemiologic variable and risk factor for specific pathogens and outcomes in patients with HAP and VAP. Early-onset HAP and VAP are defined as occurring within the first 4 days of hospitalization, usually carry a better prognosis, and are more likely caused by antibiotic-sensitive bacteria. Late-onset HAP and VAP (occurring after ≥5 days of hospitalization) are more likely to be caused by multidrug-resistant (MDR) pathogens and are associated with increased morbidity and mortality.[48]

Pathogenesis

Microorganisms gain access into the lower respiratory tract via aspiration of oropharyngeal pathogens and leakage of secretions around the endotracheal tube cuff in intubated patients.[80],[81] Invasive-care devices, contaminated equipment, and transfer of microorganisms among staff and patients serve as the primary

pathogen sources,[82] and although more controversial, the gastrointestinal tract may also play a role in bacterial colonization.[83]

Clinical Presentation and Diagnosis

HAP and VAP are diagnosed based on radiographic findings, clinical features, and health care setting when there is initial evidence of infection. Patients must demonstrate new or progressive infiltrates on imaging as well as two of three of the following signs: fever >100.40 °F (>38 °C), leukopenia or leukocytosis, and purulent sputum. Patients will often experience declines in oxygen saturation, but this finding is less specific for determining the need for empiric antimicrobial agents.[84]

Respiratory cultures may be taken from endotracheal aspirates, bronchoalveolar lavage, or protected-specimen brush samples. Blood cultures lack sensitivity, and when positive, a potential extrapulmonary source should be considered.[85]

Overview of Treatment

The IDSA/ATS have published guidelines for the treatment of HAP.[48] The five major principles in the management of HAP and VAP include the following: (a) failure to initiate prompt, appropriate therapy is associated with increased mortality; (b) the variability of bacteriology from one institution to another, as well as within specific sites in a hospital, can be significant; (c) the overuse of antibiotics should be avoided by focusing on accurate diagnosis; (d) therapy should be tailored based on lower respiratory tract cultures and the duration of therapy should be shortened; and (e) prevention strategies directed at modifiable risk factors should be applied. Antimicrobial choice considers the likelihood of an infection with a potential pathogen based on the time to onset of HAP, severity of the condition, and underlying risk factors. In general, patients with early-onset disease who are not severely ill and have no risk factors for MDR organisms can be treated with a single agent, including a non-

antipseudomonal third-generation cephalosporin or an antipneumococcal fluoroquinolone (**Table 67-7**). Empiric therapy in those with late-onset or severe disease should include a combination of antibiotics active against *Pseudomonas.* This regimen usually includes an antipseudomonal β-lactam, such as cefepime, imipenem, meropenem, or piperacillin–tazobactam, plus either an aminoglycoside or ciprofloxacin/levofloxacin. Vancomycin or linezolid should be added if MRSA risk factors are present or there is a high institutional incidence (**Table 67-8**).[48]

Table 67-7

Empiric Therapy for Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia in Patients With No Known Risk Factors for Multidrug-Resistant Pathogens and Onset >5 Days

Possible Pathogens	Recommended Therapy	Dosage
Streptococcus pneumoniae[a] *Haemophilus influenza* MSSA Antibiotic-sensitive enteric GNB *Escherichia coli* *Klebsiella pneumoniae* *Enterobacter* spp. *Proteus* spp. *Serratia marcescens*	Ceftriaxone	1–2 g IV every 24 hours
	Or	
	Levofloxacin	750 mg IV every 24 hours
	Or	
	Moxifloxacin	400 mg IV every 24 hours
	Or	
	Ertapenem	1 g IV every 24 hours
	Or	
	Ampicillin–sulbactam	3 g IV every 6 hours

GNB, gram-negative bacilli; IV, intravenous; MSSA, methicillin-sensitive *Staphylococcus aureus.*

[a]The frequency of penicillin-resistant *S. pneumoniae* and multidrug-resistant *S. pneumoniae is* increasing; levofloxacin or moxifloxacin are preferred to ciprofloxacin.

Source: Kalil AC, Metersky ML, Klompas M, et al. Management of adults with hospital-acquired and ventilator-associated pneumonia: 2016 clinical practice

guidelines by the Infectious Diseases Society of America and the American Thoracic Society. *Clin Infect Dis*. 2016;63:1–51.

Table 67-8
Empiric Therapy for Hospital-Acquired Pneumonia and Ventilator-Associated Pneumonia in Patients With Late-Onset Infection (≥5 days) or Risk Factors for Multidrug-Resistant Pathogens

Possible Pathogens	Recommended Combination Therapy	Adult Dosage[a]
MDR pathogens *Pseudomonas aeruginosa* *Klebsiella pneumoniae* (ESBL+)[b] *Acinetobacter* spp.[b]	*Antipseudomonal cephalosporin* Cefepime Ceftazidime *Or* *Antipseudomonal carbapenem* Imipenem–cilastatin Doripenem Meropenem *Or* β-*Lactam*/β-*lactamase inhibitor* Piperacillin–tazobactam *Plus* *Antipseudomonal fluoroquinolone*[d] Ciprofloxacin *Or* Levofloxacin *Or* *Aminoglycoside* Amikacin Gentamicin Tobramycin	 1–2 g IV every 8–12 hours 2 g IV every 8 hours 500 mg IV every 6 hours or 1 g IV every 8 hours 500 mg IV every 6–8 hours[c] 1 g IV every 8 hours 3.375–4.5 g IV every 8 hours (infused over 4 hours) 400 mg IV every 8 hours 750 mg IV every 24 hours 15–20 mg/kg IV every 24 hours[e] 5–7 mg/kg IV every 24 hours[e] 5–7 mg/kg IV every 24 hours[e]
MRSA[d]	*Plus* Vancomycin *Or* Linezolid	15 mg/kg every 12 hours[f] 600 mg every 12 hours
Legionella pneumophila[g]	Azithromycin	500 mg IV every 24 hours

ESBL, extended-spectrum β-lactamase; IV, intravenous; MDR, multidrug-resistant; MRSA, methicillin-resistant *Staphylococcus aureus.*

[a]Dosages are based on normal renal and hepatic function.

[b]If an ESBL+ strain, such as *K. pneumoniae*, or *Acinetobacter* spp. is suspected, a carbapenem alone or in combination with a β-lactamase inhibitor (eg, meropenem–vaborbactam) is a reliable choice, or one of the newer third-generation cephalosporin combinations with a β-lactamase inhibitor (ie, ceftazidime–avibactam, ceftolozane–tazobactam), or cefiderocol alone.

[c]Studied infusion times range from 30 minutes to 4 hours.

[d]If MRSA risk factors are present, or there is a high incidence locally.

[e]Trough levels for gentamicin and tobramycin should be based on drug levels.

[f]Trough levels for vancomycin should be 15–20 µg/mL; newer guidelines recommend using a target AUC/MIC ratio of 400 to 600 for therapeutic vancomycin monitoring.

[g]If *L. pneumophila* is suspected, a combination antibiotic regimen including a macrolide (eg, azithromycin) or a fluoroquinolone (eg, ciprofloxacin or levofloxacin) should be used.

Microbiology

The major difference in the bacteriology between CAP and HAP or VAP is a shift to gram-negative pathogens, MDR pathogens, and MRSA. Gram-negative bacilli commonly colonize oropharyngeal secretions of patients with moderate-to-severe (acute and chronic) diseases without exposure to broad-spectrum antibiotics.[86] Patients admitted to the hospital with acute illnesses are rapidly colonized with gram-negative organisms. Approximately 20% are colonized on the first hospital day, and this number increases with the duration of

hospitalization and severity of illness. The respiratory tract of ~35% to 45% of hospitalized patients and up to 100% of patients who are critically ill will be colonized within 3 to 5 days of admission.[86,87]

In the past, gram-negative bacteria accounted for 50% to 70% of all cases of HAP and VAP[48,88–92]; however, gram-positive organisms have become increasingly common, with *S. aureus* responsible for upward of 40% of cases of HAP and VAP. This is in stark contrast to CAP bacteriology, in which *S. aureus* represents 25% or less of cases. *Pseudomonas aeruginosa* remains the most prevalent gram-negative organism in HAP and VAP, accounting for ~20% to 25% of infections.[93] In patients who are ventilator-dependent, *Acinetobacter* species is an increasingly common gram-negative pathogen. Other organisms with special risk factors include *Legionella*, which is associated with high-dose corticosteroid use and outbreaks secondary to water supplies and cooling systems,[87,94] and *Aspergillus*, which is associated with neutropenia or organ transplantation.[95]

Risk factors for MDR pathogens include patient-specific factors such as antimicrobial therapy in the previous 90 days, current hospitalization of 5 days or more, and immunosuppressive disease or therapy. Coverage for MDR organisms should also be initiated if there is a high frequency of community, hospital, or health care facility (ie, nursing home) antibiotic resistance.[96]

CASE 67-5

QUESTION 1: M.L. is a 71-year-old male admitted to the hospital for a deep vein thrombosis. His past medical history is significant for chronic kidney disease (CrCl 40 mL/minute), diabetes mellitus, COPD, GERD, hypertension, and a recent diagnosis of non–small cell lung cancer for which he is not currently receiving chemotherapy. M.L.'s home medications include lisinopril, famotidine, aspirin, insulin glargine, insulin aspart, tiotropium, fluticasone/salmeterol, and as-needed albuterol.

What characteristics does M.L. exhibit that place him at risk for HAP?

Several risk factors for HAP have been identified, including intubation and mechanical ventilation, aspiration, a patient's body

position, the administration of enteral feeding, prior use of antibacterial agents, gastrointestinal bleeding prophylaxis (ie, histamine type-2 antagonists and proton-pump inhibitors), immunosuppressive therapy, and poor nutrition status or glucose control. Other nonmodifiable risk factors associated with developing HAP include age older than 70 years and chronic lung disease.

An important factor in the cause of pneumonia is colonization of the oropharynx, common in alcoholism and with prolonged hospitalization, and previous antimicrobial exposure.[48] Several factors may contribute to the colonization of M.L.'s oropharynx with gram-negative bacteria. In addition to his pulmonary disease, an altered immune response in diabetics and being elderly can predispose M.L. to respiratory infection. The use of drugs that inhibit the production of gastric acid, such as famotidine and omeprazole, increases the possibility of oropharyngeal colonization and pneumonia; yet acid-suppressive medications are commonly used to prevent gastric stress ulcers in mechanically ventilated patients.[97–100]

Antibiotic Therapy

Case 67-5, Question 2: Three days after admission, while receiving anticoagulation for the deep vein thrombosis, M.L. exhibits a fever to 102.74 °F (39.3 °C). Antibiotics are inappropriately delayed, and over the next 24 hours, his respiratory function declines significantly requiring intubation (Pa_{O_2}/F_{IO_2} 250). Additionally, objective findings show elevated WBC count (17,200 cells/μL), left shift (immature leukocytes, bands 18%), and a new infiltrate on his daily chest radiograph. Sputum cultures are sent, and the decision is made to start M.L. on antibiotics. How should antimicrobial therapy be managed for M.L.?

Because delays in the administration of appropriate therapy have been associated with increased hospital mortality from HAP, the prompt administration of empiric therapy is essential. Importantly, changing therapy once culture results are available may not reduce the excess risk of hospital mortality if inappropriate initial therapy is selected.[48] To this end, available and frequently updated local bacteriologic patterns and in vitro susceptibility data should be

consulted to allow for appropriate selection of initial empirical therapy. In addition to choosing an appropriate agent, the selection of adequate dosing regimens will optimize the pharmacodynamic properties of the antibacterial agent(s) and improve clinical outcomes and mortality rates.[48]

Resolution of HAP can be defined both clinically and microbiologically. Clinical improvement usually is apparent after the first 48 to 72 hours of therapy. During this time, the selected antibacterial regimen should not be changed unless progressive deterioration takes place or microbiologic studies confirm the pathogen.

If culture results are negative or inconclusive (because of known specimen contamination with mouth flora), the patient's response to the initial antibiotic therapy should guide potential modification of the antibiotic regimen. If the patient responds to the initial regimen, narrowing coverage to the most likely causative pathogens is recommended.

If the patient is not responding to the initial antibiotic therapy, one should consider whether (a) the pathogen is not covered in the initial choice of antibiotic therapy, (b) the dose of antibiotic is insufficient, and (c) any other factors are responsible for the failure to respond to therapy. Such factors include poor pulmonary clearance of necrotic tissue and cellular debris, lung abscesses or empyema, and severely altered host defenses leading to a rapidly fatal underlying disease.

Of note, if microorganisms such as *Serratia*, *Pseudomonas*, indole-positive *Proteus*, *Citrobacter*, or *Enterobacter* species are isolated, in vitro susceptibility reports should be carefully evaluated, as these organisms often possess an inducible β-lactamase gene (also referred to as a type-I β-lactamase enzyme).[101] In vitro testing may demonstrate susceptibility to third-generation cephalosporins and extended-spectrum penicillins, but this may not translate into efficacy in the clinical setting. As a possible scenario of infection with these organisms, after initiation with one of the above agents, the patient may initially respond; however, after ~1 week, the patient's condition begins to worsen. Because treatment with the β-lactam agent induces the expression of the type-I enzyme, a subsequent

sputum specimen (sent after ~1 week) is now likely to demonstrate resistance to the third-generation cephalosporins and extended-spectrum penicillins.[101] Although cefepime is more likely to be active against these isolates, a large inoculum of organisms (eg, present in pneumonia) can result in β-lactamase degradation of this agent as well.[102] Considering that this phenomenon will not be identified by usual in vitro testing, cefepime should be used cautiously in these patients.[103] The preferred therapy in these patients includes trimethoprim–sulfamethoxazole, a fluoroquinolone, or a carbapenem.[101] *Acinetobacter* species are increasingly resistant to many commonly used antibacterial agents. Treatment of this often MDR pathogen requires the use of very high doses of ampicillin–sulbactam (up to 24 g/day) or colistin.[104],[105] Since publication of the 2016 IDSA guidelines on managing HAP and VAP, there have been several newer β-lactam/β-lactamase inhibitors that have been approved for MDR gram-negative pathogens including ceftazidime–avibactam, ceftolozane–tazobactam, and cefiderocol.

Case 67-5, Question 3: Seventy-two hours after initiation of empiric antibiotics, the microbiology laboratory reports that >100,000 colonies/mL of MRSA have grown on M.L.'s sputum culture. Antibiotics are de-escalated to vancomycin therapy alone, to which the isolate is susceptible. After a loading dose and aggressive maintenance regimen, vancomycin trough concentrations are 17 to 22 µg/mL. However, M.L. remains febrile, demonstrates progression of his infiltrates on chest radiograph, and has acute worsening of renal function requiring dialysis and necessitating vancomycin dose adjustment. Repeat tracheal cultures again grow only *S. aureus* with susceptibility to vancomycin, sulfamethoxazole–trimethoprim, daptomycin, and linezolid. Should M.L.'s antibiotic therapy be modified?

The first IDSA MRSA infection treatment guidelines[106] were published in 2011, and vancomycin therapeutic monitoring guidelines were jointly developed and recently updated by the American Society of Health-System Pharmacists, the Society of Infectious Diseases Pharmacists, and the IDSA.[107]

For MRSA pneumonia, IV vancomycin, or linezolid 600 mg by mouth (PO) or IV twice daily, or clindamycin 600 mg PO or IV three

times daily (if the strain is susceptible) is recommended for 7 to 21 days, depending on the extent of infection. Daptomycin should not be used for the treatment of MRSA pneumonia, because its activity is inhibited by pulmonary surfactant, rendering it inactive in the treatment of lung infection.[106]

VANCOMYCIN

The recommended dosing of IV vancomycin is 15 to 20 mg/kg/dose (actual body weight) every 8 to 12 hours, not to exceed 2 g/dose, for patients with normal renal function. A loading dose of 25 to 30 mg/kg (actual body weight) may be considered. Some patients may experience an adverse event during the infusion of vancomycin known as red man syndrome. Extending the infusion time to 2 hours for larger doses or premedicating patients who have experienced this phenomenon with an antihistamine may alleviate this adverse event.[106] Updated guidelines recommend the shift away from trough-only monitoring to area under the curve to minimum inhibitory concentration (AUC/MIC) ratio in patients with suspected or definitive serious MRSA infections. Assuming a vancomycin MIC of 1 mg/L, the target AUC/MIC ratio is 400:600 using Bayesian software programs to achieve clinical efficacy and maximize patient safety.[107]

LINEZOLID

Linezolid achieves higher concentrations in lung epithelial fluid than in plasma[108] and serves as an alternative to vancomycin for the treatment of MRSA pneumonia. A retrospective analysis of two prospective trials[109],[110] for the treatment of HAP found that patients in the subgroup of MRSA cases randomly assigned to linezolid experienced higher cure rates and lower mortality compared with vancomycin.[111] In contrast, a meta-analysis of eight randomized control trials comparing glycopeptide antibiotics to linezolid for suspected MRSA pneumonia found no evidence to support superiority of linezolid.[112] The ZEPHyR study compared linezolid with vancomycin in patients with proven nosocomial MRSA pneumonia in a randomized, double-blind fashion. This is the largest trial

conducted in this population to date, and it showed a statistical improvement with linezolid in clinical outcomes at the end of study; yet the confidence interval was close to no significance and only showed a benefit with linezolid in identified nosocomial MRSA pneumonia.[113] These results make it difficult for initial selection over vancomycin for empiric therapy of MRSA coverage. Therefore, it remains uncertain whether linezolid or vancomycin should be considered superior.

M.L. is at risk for MDR pathogens (current hospitalization of 5 days or more and immunosuppressive diseases) and should be started empirically on an anti-MRSA agent (vancomycin), and double coverage for resistant gram-negative pathogens (cefepime and gentamicin or ciprofloxacin) (Table 67-8). Dosing and frequency of antimicrobial agents will require renal adjustments because of M.L.'s chronic renal issues. When culture results are known, the antibiotic regimen can be modified and individualized. For patients with uncomplicated HAP or VAP, who have received appropriate empiric antibiotics with a satisfactory subsequent clinical response, 7 to 10 days of therapy is recommended.[48] However, patients infected with nonfermenting gram-negative bacilli (eg, *Pseudomonas* and *Acinetobacter*) may benefit from longer courses (14 days or greater) to prevent recurrence.[114] M.L.'s clinical response should be monitored to determine whether the selected antibiotics are effective in treating this infection. These parameters include the ability to discontinue mechanical intubation and decreases in temperature and WBC count with resolution of the left shift.

Because M.L. remains febrile despite MRSA sensitivities to vancomycin with appropriate trough concentrations, it is appropriate to consider alternative MRSA coverage. Despite MRSA susceptibility to daptomycin, the drug does not penetrate lung surfactant, and therefore it is not appropriate to use in the treatment of pneumonia. Sulfamethoxazole–trimethoprim is a less appealing option owing to the patient's dialysis requirement. M.L. should receive linezolid. Linezolid quickly reaches high lung concentrations and is safe to use in the setting of acute renal failure. Linezolid has been associated with thrombocytopenia and neutropenia. Platelet counts and WBC

should be monitored at baseline and at least every 7 days during treatment.

ALTERNATIVE AGENTS

Doxycycline, clindamycin, and sulfamethoxazole–trimethoprim are not reliably active against MRSA strains, and recent research has focused on novel agents. Although active against MRSA, tigecycline has been associated with worsened clinical outcomes when used for the treatment of HAP, including MRSA pneumonia.[115] Telavancin has been compared with vancomycin in the treatment of HAP caused by gram-positive pathogens. Treatment with telavancin achieved higher clinical cure rates in patients with monomicrobial *S. aureus* infection and in those with isolates that demonstrated a vancomycin MIC of at least 1 μg/mL. However, lower cure rates were observed in the telavancin group in those who had mixed infections. Telavancin use was also associated with a higher incidence in serum creatinine elevation; yet in 2013, the U.S. FDA approved the drug for HAP when other alternatives are not suitable.[116]

AMINOGLYCOSIDES

Individualization of aminoglycoside dosing is imperative as the therapeutic outcome (efficacy and toxicity) of aminoglycosides correlates with plasma concentrations in patients with gram-negative pneumonia.[117–120] In patients receiving multiple daily doses of gentamicin or tobramycin and achieving a 1-hour postinfusion peak plasma concentration of >7 μg/mL, a successful outcome occurs more often than in those with lower plasma concentrations.

The aminoglycosides are concentration-dependent killing antibiotics. The rate and extent of killing organisms is maximized by increasing their peak serum concentration as high as possible relative to the MIC of the pathogen. In addition to maximizing bactericidal activity, in vitro evidence has demonstrated that this concentration goal also minimizes the development of resistance. The use of once-daily dosing strategies to minimize nephrotoxicity of the aminoglycosides has been studied extensively. Single doses of

gentamicin and tobramycin (5–7 mg/kg/day) and of amikacin (15–20 mg/kg/day) have been reported to be as effective as standard dosing (smaller single doses given every 8 or 12 hours) of these agents in controlled clinical trials. However, none of the trials has enrolled a sufficient number of patients required to demonstrate a lower incidence of nephrotoxicity. There are several advantages of once-daily dose aminoglycoside therapy: (a) it is not more nephrotoxic than traditional dosing; (b) clinicians are ensured that a therapeutic peak serum level will be achieved with the first dose; (c) it is the only safe and effective way to achieve serum peak levels of 10 to 20 times the MIC for difficult-to-treat organisms such as *P. aeruginosa*; and (d) it is a more efficient dosing regimen (fewer doses and administration times per day; fewer serum level measurements are required).[48]

Despite the use of individualized aminoglycoside dosing, morbidity and mortality rates attributable to gram-negative pneumonia remain high. This is because the success of antibiotic therapy depends on the ability of the antibiotic to reach the site of infection and remain biologically active.[120] Concentrations of the aminoglycosides in bronchial secretions range from 1 to 5 µg/mL (30%–40% of serum concentrations) 2 to 4 hours after parenteral administration.[121],[122] These concentrations may be insufficient to inhibit the growth of many gram-negative organisms, especially *Pseudomonas*. Lastly, aminoglycosides bind to purulent exudates and cellular debris and are inactivated by these agents.[123–125]

In summary, the aminoglycosides penetrate poorly into bronchial secretions and are less active at the site of infection because of local pH effects and binding to cellular debris. These properties may result in the need for increased dosages, placing patients at increased risk for ototoxicity and nephrotoxicity. Therefore, unless no reasonable alternative exists, aminoglycoside monotherapy for the treatment of pneumonia should be avoided.

INHALED AGENTS FOR MULTIDRUG-RESISTANT PATHOGENS

Because of the growing incidence of pneumonia caused by MDR gram-negative organisms, there is renewed interest in the use of inhaled aminoglycosides and polymyxin products. When given systemically, both classes have been associated with poor pulmonary penetration and with nephrotoxicity, with polymyxin carrying the additional risk of neurotoxicity, and with aminoglycosides ototoxicity. However, the proposed high drug concentrations at the site of pulmonary infection, minimal systemic exposure after nebulized administration, and data showing benefit in both the prevention and treatment of *Pseudomonas* pulmonary infection in patients with cystic fibrosis make aerosolized antibiotic therapy an appealing strategy for the treatment of VAP. The IDSA/ATS guidelines state that aerosolized antimicrobials be considered in patients with MDR organisms not responding well to IV therapy.[48]

The use of adjunctive inhaled antibiotics in VAP has been evaluated in several studies. A systematic review of 16 observational studies and randomized trials without blinding revealed that aerosolized colistin was associated with microbial eradication (OR, 1.61; 95% CI, 1.11–2.35) and improved clinical response (OR, 1.57; 95% CI, 1.14–2.15) but the results were limited by several biases.[126] A systematic review of 12 observational and randomized trials with some blinding showed that nebulized antibiotics in patients with VAP had some benefit in patient outcomes. Nebulized antibiotics were associated with increased rate of clinical cure (RR, 1.23; 95% CI, 1.05–1.43).[127] Neither study showed an improvement in mortality, duration of mechanical ventilation, or length of stay in the intensive care unit.

ALTERNATIVE DOSING OF ANTIBIOTICS FOR MULTIDRUG-RESISTANT PATHOGENS

Carbapenems, cephalosporins, and extended-spectrum penicillins or β-lactamase inhibitors demonstrate time-dependent killing, and it is known that bactericidal killing for these drug classes is optimized if their free drug concentrations are greater than the MIC for 30% to 40%, 50% to 60%, and 60% to 70% of the time, respectively.

Prolonged or continuous infusions have been used to increase the time that free drug concentrations are greater than the MIC, theoretically leading to improved patient outcomes.[128]

Continuous infusions were first used in the late 1970s with suggested improvement in clinical cure rates,[129] but until recently they were largely abandoned owing to logistical concerns about medication stability, drug compatibility, and limited IV access. These concerns are lessened by use of contemporary prolonged infusions. This latter strategy is supported primarily by Monte Carlo simulation, a mathematical modeling technique that estimates the probability of pharmacodynamic target attainment at each MIC for a given MIC range.

Patients diagnosed with VAP and treated with cefepime 2 g every 8 hours (3-hour infusion) have been evaluated using the Monte Carlo methodology. Investigators found that at an MIC of 1 μg/mL, all regimens had a probability of target attainment >90%. However, at an MIC of 8 μg/mL, when compared with 30-minute intermittent infusions of 1 to 2 g every 8 hours and 2 g every 12 hours, only the prolonged infusion (3 hours) of 2 g every 8 hours maintained 90% probability of target attainment. As one might predict, this phenomenon was only demonstrated in patients with preserved renal function as defined as a creatinine clearance of 50 to 120 mL/minute.[129]

A comparison of intermittent and continuous infusion dosing strategies was also done with piperacillin–tazobactam to treat *Pseudomonas* infections. Lodise et al retrospectively compared intermittent infusions of 3.375 g IV piperacillin–tazobactam (infused over 30 minutes every 6 hours) versus extended infusions of 3.375 g IV piperacillin–tazobactam (infused over 4 hours every 8 hours).[130] Results indicated a shorter length of hospital stay (21 vs 38 days; P = .02) and lower 14-day mortality rate among patients with Acute Physiological and Chronic Health Evaluation-II scores >17 (12.2% vs 31.6%; P = .04) in patients receiving extended infusion therapy.[130]

Ventilator-Associated Pneumonia Prophylaxis

The substantial risk of pneumonia in the ICU has prompted aggressive methods to prevent this disease.[131],[132] The most important recommendations include the use of the semi-upright position to reduce the risk of aspiration, infection control (including hand washing) to prevent the spread of pathogens from one patient to the next, and surveillance for ICU infections.[132]

Several strategies for the prevention of VAP are controversial, including selective decontamination of the digestive tract (SDD), selective oral decontamination (SOD), and topical antiseptics applied to the oral mucosa. These three strategies address the concept that VAP occurs after colonization of the upper respiratory tract. Because digestive tract flora may play a role in this colonization, the impact of various decontamination approaches has been studied. For SDD, a combination therapy including topical tobramycin, polymyxin E, and, sometimes, amphotericin B is administered to the stomach and oropharynx four times daily in combination with IV administration of ciprofloxacin or a second-generation cephalosporin. SOD uses a similar antimicrobial strategy to SDD, except that the IV agents are omitted, and the combination therapy is applied to the oropharynx.

Historically, SDD and SOD are more widely used in Europe, and most of the literature investigating these techniques in thousands of patients and supporting their use results from outside the United States. In 2009, De Smet et al performed a large crossover study comparing standard of care ventilation bundles versus SDD versus SOD in mechanically ventilated patients and found a statistically reduced risk of 28-day mortality with an OR of 0.83 (95% CI, 0.72–0.97) for SDD and 0.86 (95% CI, 0.74–0.99) for SOD.[133]

In 2015, Roquilly et al produced the largest meta-analysis of VAP prevention techniques to decrease mortality.[134] More than 37,000 patients were involved from 157 randomized trials. Although the overall mortality reduction was 5% in the intervention group, in a subgroup analysis only SDD significantly decreased mortality compared to control with an RR of 0.84 (95% CI, 0.76–0.92).[134] Despite the overwhelming evidence supporting SDD, leading clinicians suggest there are still concerns of North American practitioners who fear that widespread use of antibiotics for SDD will

increase antibiotic resistance and *Clostridioides difficile* infections, particularly in the United States where drug resistance is more prevalent than in Northern Europe.[135]

Tuberculosis

Michael B. Kays

CORE PRINCIPLES		CHAPTER CASES
1	Tuberculosis is an infectious disease caused by *Mycobacterium tuberculosis,* and the most common site of infection is the lungs. Active disease is characterized by fever, chills, cough, night sweats, weight loss, and changes on chest radiography. Several risk factors have been identified, including immune suppression, exposure to infected close contacts, and smoking.	**Case 68-1 (Questions 1, 2)**
2	Diagnosis of active disease includes chest radiography, sputum collection for acid-fast bacilli smear microscopy and culture, and nucleic acid amplification tests. Tuberculin skin testing and interferon-γ release assays may aid in the diagnosis of tuberculosis. Human	**Case 68-1 (Questions 3–7)**

	immunodeficiency virus (HIV) screening is recommended for all patients with tuberculosis.	
3	Goals of therapy include cure, prevention of transmission, and prevention of resistance of *M. tuberculosis*. Treatment of active pulmonary disease requires administration of multiple-drug therapy for a minimum of 26 weeks. Rapid molecular drug susceptibility testing for rifampin is recommended. Directly observed therapy is a core management strategy for all patients to ensure adherence to therapy.	**Case 68-1 (Questions 8–13)**
4	Patients should be monitored for resolution of symptoms and questioned about the occurrence of adverse events, especially hepatitis. Sputum smears and cultures should be obtained every 2 to 4 weeks initially and then monthly after culture results become negative. If treatment failure occurs, at least three new drugs should be added to the treatment regimen.	**Case 68-1 (Questions 14, 15)**
5	Patients with latent tuberculosis infection have a positive tuberculin skin test or interferon-γ release assay result but no clinical symptoms or radiographic evidence of active disease. Isoniazid for 6 to 9 months has been preferred historically, but rifampin for 4 months	**Case 68-2 (Questions 1, 2)**

	and weekly isoniazid plus rifapentine for 12 weeks are acceptable alternatives.	
6	Adverse events associated with isoniazid include hepatotoxicity and peripheral neuropathy. Rifampin is associated with hepatotoxicity, flulike syndrome, thrombocytopenia, and discoloration of body fluids. Pyrazinamide can cause hepatotoxicity and increased uric acid, whereas ethambutol can cause optic neuritis.	**Case 68-3 (Questions 1–3) Case 68-4 (Question 1)**
7	The case rate for tuberculosis in persons age 65 years or older is greater than that in all other age groups. Principles of treatment of tuberculosis in the elderly are the same as those for other age groups.	**Case 68-5 (Question 1)**
8	Multidrug-resistant tuberculosis can develop as a result of nonadherence to treatment. Successful treatment of multidrug-resistant tuberculosis is possible depending on the host, adherence to therapy, and the number of drugs to which the organism remains susceptible. Treatment with at least five drugs may be required in the intensive phase.	**Case 68-6 (Questions 1, 2)**
9	HIV infection is an important risk factor for tuberculosis. Clinical manifestations in HIV-infected persons will vary depending on the severity of immunodeficiency at presentation.	**Case 68-7 (Questions 1–3) Case 68-8 (Question 1)**

	Principles and recommendations for treatment of active disease and latent infection in HIV-infected persons are the same as those for HIV-negative persons.	
10	In antiretroviral-naive patients, the optimal timing for initiating antiretroviral therapy is dependent on the patient's $CD4^+$ cell count. Antiretroviral therapy may be delayed to decrease the potential for immune reconstitution inflammatory syndrome. If patients are receiving antiretroviral therapy, treatment of tuberculosis should begin immediately with modification of antiretroviral therapy as needed.	**Case 68-7 (Questions 4, 5)**
11	Treatment of active disease in pregnant females is the same as that for nonpregnant females. Pyrazinamide is not recommended in pregnancy in the United States owing to insufficient safety data. However, pyrazinamide is frequently utilized in other countries. Minimum duration of therapy is 9 months without pyrazinamide.	**Case 68-9 (Question 1)**
12	Infants and children have a higher risk of disseminated tuberculosis, and treatment should be initiated promptly. Ethambutol is generally avoided because it is difficult to assess visual acuity in children. Many experts prefer to initiate therapy in children with three	**Case 68-10 (Question 1)**

	drugs and treat for a minimum duration of 6 months.	
13	Extrapulmonary tuberculosis may require longer durations of therapy. Tuberculous meningitis may require 9 to 12 months of therapy, and corticosteroids reduce sequelae and improve survival.	**Case 68-11 (Question 1)**

INTRODUCTION

Tuberculosis (TB) is an ancient disease with evidence of spinal TB in pre-Columbian and early Egyptian remains. TB emerged as a major health problem in the 17th and 18th centuries when crowded living conditions of the Industrial Revolution contributed to its epidemic spread throughout Europe and the United States. Early physicians referred to TB as *phthisis,* derived from the Greek term for wasting, because its clinical presentation consisted of weight loss, cough, fevers, and hemoptysis. The etiologic agent was identified in 1882 when Robert Koch isolated and cultured *Mycobacterium tuberculosis* and demonstrated its infectious nature. With this knowledge, early treatment in the mid-1800s to the early 1900s consisted of placing patients with TB in a sanatorium for bed rest and fresh air. With the advent of radiographic film, pulmonary cavitary lesions were found to be a pivotal component in the evolution of the disease. Therapy included pneumoperitoneum, thoracoplasty, and plombage to reduce the size of the cavitary lesion, and some of these therapies are still used today for severe and refractory cases.

The modern era of medical TB therapy began in 1944 with the discovery of streptomycin and, shortly thereafter, *p*-aminosalicylic acid. Addition of isoniazid in 1952 and rifampin in the late 1960s greatly increased treatment success and provided hope for the eventual elimination of TB. However, multidrug-resistant tuberculosis

(MDR-TB) emerged in the 1990s as a threat to the control of TB in the United States and other countries.[1–3] In the subsequent decade, published reports described the worldwide emergence of extensively drug-resistant tuberculosis (XDR-TB)[4–6] and, more recently, the emergence of totally drug-resistant (TDR) or super XDR-TB strains.[7] As TB strains become increasingly resistant to currently available agents, the likelihood of achieving global control and elimination of this disease is diminished. Therefore, a high index of suspicion for TB, rapid pathogen identification, susceptibility testing, patient isolation, and appropriate antimicrobial therapy are critical to prevent further development and spread of drug-resistant TB.

Incidence and Epidemiology

Assuming lifelong infection, ~2.0 billion people (30% of the world's population) are infected with *M. tuberculosis.*[8] TB is one of the top 10 causes of death worldwide and the leading cause of death from a single infectious agent, ranking above human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS).[9] Globally, there were an estimated 10 million new cases of TB in 2019; the majority of these new cases were identified in Southeast Asia, Africa, and the Western Pacific.[9] Approximately 8.2% of the new TB cases in 2019 were identified in persons living with HIV, with the African region accounting for 86% of these cases.[9] In 2019, ~1.2 million deaths were reported among HIV-negative cases (decreased from 1.7 million in 2000) and 0.21 million deaths were reported among HIV-positive cases (decreased from 0.68 million in 2000).[9]

In the United States, 7163 cases of TB were provisionally reported in 2020, and the incidence rate was 2.2/100,000 population, which represents the lowest recorded rate since national reporting began in 1953.[10] However, the incidence rate remained higher than the national goal for elimination of TB (<1 case per 1,000,000 population). Thirty-nine states and the District of Columbia reported decreased TB cases in 2020, and four states (California, Texas, New York, and Florida) accounted for >50% of all TB cases.[10] The number

of TB cases and incidence rates declined for both foreign-born and U.S.-born persons, but foreign-born and ethnic and racial minorities continue to be disproportionally affected by TB in the United States. In 2020, 71% and 29% of all TB cases were reported in foreign-born and U.S.-born persons, respectively, and the incidence rate was >16 times higher in foreign-born persons compared with U.S.-born persons (11.5 vs 0.7 per 100,000 population).[10] Mexico, the Philippines, India, Vietnam, and China were the most frequently reported countries of birth among foreign-born persons.[10] Among U.S.-born persons, the greatest number of TB cases was reported in non-Hispanic Blacks. Among persons with TB whose HIV status was known, 4.7% of these patients were coinfected with HIV in 2019.[11]

In the United States, 9.2% of isolates from patients with no previous history of TB were resistant to isoniazid in 2019; resistance was 6.5% in U.S.-born individuals and 10.2% in foreign-born individuals.[11] In 2019, there were ~206,000 global cases of MDR-TB, defined as resistance to both isoniazid and rifampin, and 3.3% of new TB cases and 17.7% of previously treated cases were caused by MDR-TB.[9] The largest number of MDR-TB cases were reported in India, China, and the Russian Federation.[9] In the United States, 90 cases of MDR-TB were reported in 2019, and foreign-born persons accounted for 86% of these MDR-TB cases.[11] The percentage of MDR-TB cases is approximately five times higher for persons with a previous history of TB compared with persons with no previous history of TB.[11] Several conditions and risk factors for persons with increased risk of infection with drug-resistant TB are shown in **Table 68-1**.

Table 68-1
Conditions and Risk Factors for Persons With Increased Risk of Drug-Resistant Tuberculosis

History of treatment for latent tuberculosis infection or active disease
Patients from areas with high prevalence of initial or primary drug resistance (urban population, northeast United States, Florida, California, Texas, United States–Mexico border)

Foreign-born persons from areas with high prevalence of drug-resistant tuberculosis (Southeast Asia, Mexico, South America, Africa)
Contact with persons with active infection caused by drug-resistant *Mycobacterium tuberculosis*
Tuberculosis in persons who are homeless, abusers of intravenous drugs, and HIV infected
Patients with positive sputum smear and culture results after 2 months of treatment

HIV, human immunodeficiency virus.

In the mid-2000s, XDR-TB emerged as another major threat to global health.[4–6] The definition of XDR-TB is resistance to isoniazid and rifampin among first-line agents, resistance to any fluoroquinolone, and resistance to at least one second-line injectable drug (amikacin, kanamycin, or capreomycin).[12] Globally, 12,350 cases of TB were caused by XDR-TB strains in 2019.[9] One of the first reports described 53 patients infected with XDR-TB from South Africa.[13] HIV status was known in 44 patients, and all of these patients were HIV positive. Fifty-five percent of the patients had no prior history of TB treatment, and 98% died with a median survival period of only 16 days after collection of the first sputum specimen.[13] In the United States, 63 cases of XDR-TB were identified between 1993 and 2011, and mortality was strongly associated with concomitant HIV infection.[14] In 2019, four cases of XDR-TB were reported in the United States.[11]

Risk factors for XDR-TB include previous treatment for TB, HIV infection, homelessness, and alcohol use.[15] In a retrospective analysis of patients with documented MDR-TB, emergence of XDR-TB was associated with baseline chronic disease and nonadherence to MDR-TB therapy.[16] Treatment success is significantly lower for XDR-TB, and XDR-TB is associated with increased all-cause and TB-related mortality.[17] However, treatment outcomes are significantly improved when later generation fluoroquinolones are added to the treatment regimen, even if fluoroquinolone resistance was demonstrated on susceptibility testing.[18]

The evolution of TB resistance continued in 2009 with the identification of strains that were reported to be TDR, which was defined as resistance to all first-line and second-line agents.[7] Fifteen (10.3%) of 146 MDR-TB strains tested were found to be TDR-TB in Iran, and culture results remained positive in these cases after 18 months of treatment with second-line agents.[7] All of these TDR-TB cases were HIV negative. This report illustrates the critical need to develop new and effective agents for the treatment of TB caused by MDR, XDR, and TDR strains.

Etiology

TB is caused by *M. tuberculosis,* an aerobic, non-spore–forming bacillus that resists decolorization by acid alcohol after staining with basic fuchsin. For this reason, the organism is often referred to as an acid-fast bacillus (AFB).

M. tuberculosis is different from other bacteria in that it replicates slowly—once every 24 hours instead of every 20 to 40 minutes as with some other bacteria. The organism thrives in environments in which the oxygen tension is relatively high, such as the apices of the lung, the renal parenchyma, and the growing ends of bones.

Transmission

M. tuberculosis is transmitted through the air by aerosolized droplet nuclei that are produced when a person with pulmonary or laryngeal TB coughs, sneezes, speaks, or sings. Droplet nuclei may also be produced by other methods, such as aerosol treatments, sputum induction, bronchoscopy, endotracheal intubation, suctioning, autopsy, and through manipulation of lesions or processing of secretions in the hospital or laboratory.[19] These droplet nuclei, which contain one to three *M. tuberculosis* organisms, are small enough (1–5 μm) to remain airborne for prolonged periods and reach the alveoli within the lungs when inhaled. Tubercle bacilli are not

transmitted on inanimate objects, and organisms deposited on skin or intact mucosa do not invade tissues.

Several factors influence the likelihood of transmission of *M. tuberculosis,* including the number of organisms expelled into the air by the index patient, the concentration of organisms in the air determined by the volume of the space and its ventilation, the length of time an exposed person breathes the contaminated air, location of the exposure (small room vs outdoors), and the immune status of the exposed individual.[20] Family household contacts, especially children, and persons working or living in an enclosed environment (eg, hospitals, nursing homes, prisons) with an infected person are at increased risk for becoming infected. If the index case finding is smear positive, 50% of household contacts will have a conversion of the tuberculin skin test (TST) result from negative to positive; however, if the index case finding is smear negative, only 5% will become infected.[20] Individuals with impaired cell-mediated immunity, such as HIV-infected persons or patients who underwent transplant, are more likely to become infected with *M. tuberculosis* after exposure than are persons with normal immune function.[20] Travelers to TB-endemic areas with international medical exchange programs are also at risk for TB infection, regardless of the involvement in direct patient care activities or duration of stay.[21]

Several techniques are effective in limiting airborne transmission of *M. tuberculosis* by reducing the number of droplet nuclei in a given airspace. Adequate room ventilation with fresh air is very important, especially in the health care setting, in which six or more room air exchanges per hour are desirable.[19],[22] New construction or renovation of existing facilities should be designed so that airborne infection isolation rooms achieve ≥12 room air exchanges per hour.[22] Ultraviolet irradiation of air in the upper part of the room can also reduce the number of viable airborne tubercle bacilli. All health care workers and visitors who enter the room of a patient with infectious TB should wear at least N95 disposable respirators, and the mask should be molded to fit tightly around the nose and mouth.[22] Patients with presumed or confirmed infectious TB should wear a protective mask when being transferred to another area of the institution or

after hospital discharge until they are noninfectious.[22] However, the most important means of reducing transmission of *M. tuberculosis* is by treating the infected patient with effective antituberculosis therapy.

Pathogenesis

LATENT INFECTION VERSUS ACTIVE DISEASE

Latent infection

A clear distinction should be made between latent infection and active disease. Latent infection occurs when the tubercle bacilli are inhaled into the body. After inhalation, the droplet nuclei containing *M. tuberculosis* settle into the bronchioles and alveoli of the lungs. Development of infection in the lung is dependent on the inoculum of organisms inhaled, the virulence of the organism, and the innate immune response of the host.[23–25] In the nonimmune (susceptible) host, the bacilli initially multiply unopposed by normal host defense mechanisms. Organisms are then phagocytized by alveolar macrophages and resident dendritic cells, but they may remain viable, multiplying within the cells for extended periods.[25] After 14 to 21 days of replication, the tubercle bacilli spread via the lymphatic system to the hilar lymph nodes and through the bloodstream to other organs of the body.

Fortunately, certain organs and tissues in the body, such as the bone marrow, liver, and spleen, are resistant to subsequent multiplication of these bacilli. Organs with high blood flow and Pa_{O_2}, such as the apices of the lungs, kidneys, bones, and brain, are favorable for organism growth and may lead to extrapulmonary disease. Organisms replicate for 2 to 12 weeks until they reach a concentration of 10^3 to 10^4, plateauing coincident with the development of T-cell–mediated immunity in the host.[25] $CD4^+$ T cells produce interferon-***γ***, which is an essential cytokine for activation of macrophages and mycobacterial killing.[25] At this point, the patient has developed cell-mediated immunity, which can be detected by a reaction to the TST or interferon-γ release assay (IGRA), and bacterial replication is halted.[25]

In persons with intact cell-mediated immunity, activated T cells and macrophages may result in granuloma formation, a hallmark of TB, that is thought to represent a physical and immunologic barrier to control the infection and limit dissemination of the bacilli to the surrounding environment.[25] Cells found within the granuloma include $CD4^+$ and $CD8^+$ T cells, B cells, neutrophils, macrophages, multinucleated giant cells, and fibroblasts.[25] Organisms tend to localize in the center of the granuloma, which is frequently necrotic, and the tubercle bacilli may remain viable indefinitely within the granuloma. In addition, maintenance of the integrity of the granuloma allows for control of bacterial replication and depends on the immune status of the patient.[25] Tumor necrosis factor (TNF) is a critical cytokine for the integrity of the granuloma.[26] Most patients with latent TB infection are asymptomatic, with no radiographic evidence of the infection.[23] In some patients, there may be a healed, calcified lesion on the chest radiograph, but bacteriologic studies return negative results. A positive TST or IGRA finding is the only indication that the person has been infected with *M. tuberculosis.* Individuals with latent TB infection are not infectious and thus cannot transmit the organism to other individuals.[19]

Active disease

In the majority of patients, active TB disease results from reactivation of a previously controlled latent infection, termed *reactivation TB*. It has been estimated that ~10% of individuals who acquire TB infection and do not receive therapy for the latent infection will develop active TB disease, and the risk of developing active disease is greatest during the first 2 years after infection.[18,23,24] In a population-based TST survey conducted in Florida between 1997 and 2001, the rate of reactivation with latent TB infection without HIV coinfection was 0.040 to 0.058 cases per 100 person-years.[27] However, another study reported that one in four cases of active TB in the United States may be caused by recent transmission.[28] This study included patients with TB whose culture result was positive, and *M. tuberculosis* isolates were fully characterized by genotype.

Clusters were defined as cases with *M. tuberculosis* that were an exact match by genotype within specific geospatial zones. Cases that were both genotypically and spatially clustered were considered recent TB transmission, and cases that were not genotypically and spatially clustered were considered reactivation TB. Of the 36,860 cases where genotyping was performed, 8499 cases (23.1%) met the criteria for recent TB transmission.[28] Groups at greatest risk for recent transmission were HIV-infected individuals, members of a minority group or ethnic race, males, individuals born in the United States, children ages 4 years and younger, substance abusers, and the homeless.[28] These patients may have limited access to health care, resulting in delayed diagnosis and extended periods of infectivity.

Reactivation of TB in persons with latent TB infection is primarily a function of the immune status of the host. The ability of the host to respond to *M. tuberculosis* infection is reduced by certain diseases, such as diabetes mellitus, silicosis, chronic renal failure, and diseases or drugs associated with immunosuppression (eg, HIV infection, anti-TNF-α agents, organ and hematologic transplantation, corticosteroids, and other immunosuppressive agents). The likelihood of progression from latent TB infection to active TB disease is greater in persons with these conditions.[23–25] HIV-infected persons, especially those with low $CD4^+$ T-cell counts, develop active TB disease rapidly after becoming infected; up to 50% of these individuals may develop active disease in the first 2 years after infection.[29] In addition, a person with untreated latent TB infection who acquires HIV infection will progress to active TB disease at an approximate rate of 5% to 10% per year.[30,31] The relative risk of progression from latent infection to active disease is 1.6 to 25 times higher in patients treated with anti-TNF-α agents, depending on the clinical setting and the agents used.[32] Physical or emotional stress, gastrectomy, intestinal bypass surgery, alcohol abuse, hematologic disease, reticuloendothelial disease, and intravenous (IV) drug use are risk factors for development of active disease. The elderly, adolescents, and children younger than age 5 years are also at increased risk for developing active disease.[19,23–25,33]

Overview of Drug Therapy

Drug treatment is the cornerstone of the management of patients with TB. In a patient with active TB, the overall treatment goals are to cure the individual patient and to minimize transmission of *M. tuberculosis.* Primary goals of chemotherapy are rapid bacterial killing, prevent emergence of drug resistance, and eliminate persistent tubercle bacilli to prevent relapse.[34] To accomplish these goals, treatment must be tailored to each patient's clinical and social circumstances to ensure adherence to and completion of treatment (patient-centered care). Effective TB treatment requires a prolonged period of drug therapy, and optimization of the initial treatment phase prevents emergence of resistance and ensures success of therapy. Current guidelines recommend four drugs for the initial 8-week treatment phase: rifampin, isoniazid, pyrazinamide, and ethambutol (RIPE).[34] The drug regimen and duration of the continuation phase depends on patient response, susceptibility of the isolate, host factors, extent of the disease (pulmonary vs extrapulmonary, cavitation on chest radiography), and drug tolerability.[34] The shortest duration of therapy is 6 months, but longer durations may be required in certain situations and with drug-resistant strains.[34,35] Because patients must be treated for months, directly observed therapy (DOT) is the preferred core management strategy to ensure adherence.[34–37] In patients with latent TB infection, monotherapy with isoniazid, monotherapy with rifampin, or a combination of isoniazid plus rifapentine is among the recommended options.

Clinical Presentation of Active Disease

CASE 68-1

Question 1: H.G. is a 35-year-old Hispanic male who presents with a 4-week history of a productive cough. The cough was initially nonproductive but became productive of yellow sputum after 2 weeks. The patient has been self-medicating with over-the-counter antitussives without relief, and he experienced hemoptysis this morning. He reports subjective fevers, chills, night sweats,

dyspnea on exertion, fatigue, and an unintentional 15-pound (6.80-kg) weight loss during the past 2 months. He immigrated to the United States from Mexico when he was 12 years old, but he has not traveled outside the United States for more than a decade. He currently works as a laborer on new home construction projects, and several of his coworkers, who moved to the United States from Mexico within the past year, have similar respiratory symptoms. He is currently married with three children. The patient has a 20-pack-year smoking history and drinks alcohol on weekends but denies illicit drug use.

On physical examination, H.G. is a thin-appearing male in mild respiratory distress. His heart rate is 94 beats/minute, his respiratory rate is 24 breaths/minute, and his temperature is 102.02 °F (38.9 °C). Bronchial breath sounds are noted in the right upper lobe on chest auscultation, and chest radiography shows extensive patchy infiltrates in the right upper lobe. Significant laboratory data include the following:

White blood cell count, 13,200/μL (72% polymorphonuclear leukocytes, 3% bands, 12% lymphocytes, 13% monocytes)
Red blood cell count, 3.7×10^6/μL
Hemoglobin, 11.2 g/dL
Hematocrit, 34%
Platelets, 269×10^3/μL

Serum electrolytes, renal function, and hepatic function are within normal limits.

He is 69 inches (175.26 cm) tall, and his weight is 149.91 pounds (68 kg). The remainder of his physical examination is unremarkable.

What signs and symptoms consistent with active TB disease are present in H.G.?

H.G.'s history of cough (which gradually became productive), fever, night sweats, fatigue, and weight loss are classic symptoms of active TB.[19] Cough may be nonproductive early in the course of the illness, but with subsequent inflammation and tissue necrosis, sputum is usually produced and is key to the diagnostic studies. Sputum may contain blood (hemoptysis) in patients with advanced cavitary disease, which is particularly worrisome because cavitary lesions harbor high concentrations of organisms and the pulmonary location facilitates airborne transmission. Dyspnea is unusual unless there is extensive disease.[19] Other symptoms of TB may include pleuritic chest pain and general malaise.

In pulmonary TB, the chest radiograph usually reveals patchy or nodular infiltrates in the apical or posterior segments of the upper

lobes, but changes may be observed in any segment.

The patchy infiltrates on H.G.'s chest radiograph are consistent with pulmonary TB. Cavitary lesions may be seen; however, these were absent in this patient. Moderate elevation of the white blood cell count with increased monocytes and eosinophils and anemia are the most common hematologic manifestations of TB.[19] H.G. had an elevated white blood cell count with increased monocytes, and he was also anemic.

Many patients with active pulmonary TB have no acute symptoms, and a lack of symptoms may hinder diagnosis. In one study, ~50% of active TB cases without classic symptoms were misdiagnosed.[38] More than one-third of the patients with active TB had no sweats, chills, or malaise, and <50% were febrile. Cough was evident in 80% of these patients, and only 25% had hemoptysis. Although dullness over the apices of the lungs and posttussive rales are expected in TB, less than one-third of these patients had any abnormal pulmonary signs. Similar findings were reported in another study.[39] Absence of specific clinical symptoms underscores the importance of skin testing, sputum smears for AFB, and chest radiographs in suspected TB. Lastly, cases of active TB are often found after routine chest radiographs for other illnesses.

Because many of the symptoms of TB also occur in persons with preexisting pulmonary disease or pneumonia, they may be overlooked and not attributed to TB.

CASE 68-1, QUESTION 2: What risk factors for TB are present in H.G.?

The close contact with his coworkers, who have similar respiratory symptoms, and their geographic origin from Mexico are risk factors for TB in H.G. In addition, studies have implicated cigarette smoking as a risk factor for TB.[40–42] In a cohort study conducted in Taiwan, smoking was associated with a twofold increase in the risk of active TB. Furthermore, a significant dose–response relationship was identified for number of cigarettes smoked per day, number of years of smoking, and number of pack-years smoked.[42] Smoking impairs

mucociliary clearance, decreases phagocytic pulmonary alveolar macrophage function, decreases intracellular production of TNF-α, and causes iron overload in macrophages.[43–46] These defects in host defense mechanisms increase the risk of active disease after exposure to *M. tuberculosis.*

Diagnosis of Active Tuberculosis

Case 68-1, Question 3: A tuberculin purified protein derivative (PPD) skin test (5 test units [TU]) is ordered and placed on the volar aspect of H.G.'s left arm. Sputum is collected and sent for AFB stain, culture, and susceptibility testing. His smear finding is positive for AFB, and the result of the TST, read at 48 hours, was a palpable induration of 14 mm. What is tuberculin PPD skin testing? How should the result be interpreted in H.G.'s case?

The TST (Mantoux method) has been used as a diagnostic tool for infection with *M. tuberculosis* for decades, but a positive skin test result is not necessary for the diagnosis of active TB disease. The test is frequently referred to as the PPD test, which contains a protein prepared from a culture of the tubercle bacilli. Skin testing is performed by injecting 0.1 mL of solution containing 5 TU of PPD *intracutaneously* into the volar or dorsal surface of the forearm.[19,47] The injection is made using a 1/4- to 1/2-inch, 27-gauge needle and a tuberculin syringe. The solution should be injected just beneath the surface of the skin, avoiding subcutaneous tissue.[19,48] A discrete, pale elevation of the skin (a wheal) 6 to 10 mm in diameter is produced when the injection is performed correctly. If the first injection was administered improperly, another test dose can be given at once, selecting a site several centimeters away from the original injection site.[19]

If the patient has been infected with *M. tuberculosis,* sensitized T cells are recruited to the skin site where they release cytokines.[49] These cytokines induce an induration (raised area) through local vasodilatation, edema, fibrin deposition, and recruitment of other inflammatory cells to the area.[19] Typically, the reaction to the

tuberculin protein begins 5 to 6 hours after the injection, with maximal induration observed at 48 to 72 hours. Therefore, the test should be read between 48 and 72 hours after the injection because tests read after 72 hours underestimate the actual size of the induration.[19],[24] For standardization, the diameter of the induration should be measured transversely to the long axis of the forearm and recorded in millimeters.[19] The diameter of the induration should be measured and not the erythematous zone surrounding the induration.

An induration of at least 5 mm in diameter read 48 to 72 hours after the injection is a positive reaction in an individual with a recent history of close contact with a person with active TB, a person with fibrotic changes on chest radiograph consistent with previous TB, patients who have undergone organ transplant and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for >1 month), or HIV-infected persons.[19],[47],[50],[51]

An induration of at least 10 mm in diameter is a positive reaction with clinical conditions associated with increased risk of TB, such as diabetes mellitus, silicosis, chronic renal failure, malnutrition, leukemia, lymphoma, gastrectomy, jejunoileal bypass, and weight loss of >10% of ideal body weight.[19],[47],[51] In addition, an induration of at least 10 mm is considered to be a positive finding in recent immigrants (>5 years) from countries with a high prevalence of TB, injection drug users, residents and employees of high-risk congregate settings (eg, prisons, nursing homes, homeless shelters), health care workers, mycobacteriology laboratory personnel, and children younger than age 4 years or infants, children, and adolescents exposed to adults in high-risk categories.[19],[47],[51] The TST result is also considered positive for persons with an increase in induration diameter of at least 10 mm within a 2-year period.[47],[51] For individuals with no risk factors for TB, an induration of at least 15 mm is required for a positive reaction.[47],[51]

It is very likely that H.G. has been in close contact with persons with active TB, that is, his coworkers, even though they have not yet been diagnosed with active TB. When all factors are considered, the PPD of 14 mm should be considered to be a positive reaction in H.G.

Case 68-1, Question 4: Because H.G.'s PPD skin test result is positive, does this confirm his diagnosis of active TB? What other laboratory tests may be performed to aid in the diagnosis of TB in H.G.?

H.G.'s positive reaction to 5 TU of PPD alone does not imply active TB disease. It only confirms that he has previously been infected with *M. tuberculosis.* To confirm the diagnosis of active TB disease in H.G., *M. tuberculosis* must be detected and isolated from sputum, gastric aspirate, spinal fluid, urine, or tissue biopsy, depending on the site of infection.[19] As was performed in H.G., detection of AFB in stained sputum smears examined microscopically should be the first test to confirm the presence of mycobacteria in a clinical specimen. It is the easiest and fastest procedure that can be performed and allows preliminary confirmation of the diagnosis. Three appropriate sputum samples should be collected 8 to 24 hours apart, and at least one sample should be tested using a rapid molecular test.[34] Sputum samples for AFB stain and culture are best obtained early in the morning because the cough reflex is usually suppressed at night. The first early morning expectoration represents secretions accumulated in the chest overnight. The number of organisms in the morning sample is greater, and the diagnostic yield is higher. If a patient is not spontaneously producing sputum, induction of sputum using aerosolized hypertonic saline or bronchoscopy may be needed.[34] Smears may be prepared directly from clinical specimens or from concentrated preparations by placing the specimen on a glass slide under a microscope with a Ziehl–Neelsen or fluorochrome stain (not a Gram stain).[19] Sensitivity of sputum smear microscopy is low because 5000 to 10,000 bacilli/mL of specimen must be present for AFB detection in stained smears.[19,52] Therefore, a negative AFB smear result does not rule out active TB disease, and patients with active TB and negative AFB smear results may facilitate transmission of *M. tuberculosis.* Additional limitations of the AFB smear are its inability to differentiate among mycobacterial species and between viable and nonviable organisms. In many areas of the

United States, *M. avium* complex organisms are commonly isolated from the sputum of patients in whom a diagnosis of TB is highly probable, such as the elderly and patients with HIV infection.[53] This finding has resulted in a marked decrease in the specificity and positive predictive value of the sputum smear, in some cases to as low as 50%.[54]

The gold standard for laboratory confirmation of TB is culture.[55] Some patients may have a negative AFB smear result, but a sufficient number of organisms may be present to produce a positive culture result. Only 10 to 100 organisms are needed for a positive culture result.[19] As a result of the limitations of the AFB smear, a positive culture finding for *M. tuberculosis* is necessary to definitively diagnose TB in H.G. and all patients, even if the AFB smear result is positive. In addition, culture allows for genotyping and susceptibility testing of the isolate.[53] Because *M. tuberculosis* grows slowly (ie, once every 24 hours), it may take several weeks for the culture results to become positive.[19] Broth-based culture systems, when combined with DNA probes, can result in positive cultures in 2 weeks or less for sputum smear-positive specimens and in 3 weeks or less for smear-negative specimens.[53]

Nucleic acid amplification (NAA) tests are available to enhance and expedite direct identification of *M. tuberculosis* in clinical specimens independent of mycobacterial culture.[56],[57] These tests amplify the specific target sequences of nucleic acids in *M. tuberculosis* that can be detected by a nucleic acid probe within 24 to 48 hours. Compared with AFB smears, benefits of NAA testing include the ability to rapidly confirm the presence of *M. tuberculosis* in many AFB-negative smears and the positive predictive value of >95% for AFB-positive specimens in settings where nontuberculous mycobacteria are common.[55] NAA tests are cost-effective because they prioritize contact investigations, improve decision-making regarding respiratory isolation, and decrease unnecessary TB treatment.[58],[59] Current guidelines recommend NAA testing on at least one respiratory specimen from a patient with signs and symptoms of pulmonary TB for whom a diagnosis has not been established and for whom the test result would alter case

management and infection control activities.[55] If the NAA test result and the AFB smear result are positive, the patient is presumed to have TB, and drug treatment should be initiated while awaiting culture results.[55] If the NAA test result is positive and the AFB smear result is negative, clinical judgment should be exercised regarding initiating drug therapy, and additional diagnostic testing may be needed. If the NAA test result is negative and the AFB smear result is positive, a test for inhibitors should be performed and additional specimens should be tested with NAA. Sputum specimens (3%–7%) might contain inhibitors that prevent or reduce amplification and cause false-negative NAA results.[55] If the NAA test result and the AFB smear result are negative, clinical judgment is recommended in the decision to begin drug therapy because NAA tests lack the sensitivity in AFB smear-negative specimens needed to exclude the diagnosis of TB.[55]

Case 68-1, Question 5: Would a negative TST result have eliminated the possibility of infection with *M. tuberculosis* in H.G.?

A negative response to 5 TU of PPD in H.G. would not exclude active infection with *M. tuberculosis.* The PPD skin test has a reported false-negative rate of 25% during the initial evaluation of persons with active tuberculosis.[19] This high false-negative rate is attributable to poor nutrition and general health, overwhelming acute illness, or immunosuppression. False-negative results usually occur in persons who have only recently been infected or are anergic. Anergy, the decreased ability to respond to antigens, may be caused by severe debility, advanced age, immaturity in newborns, high fever, sarcoidosis, corticosteroids, immunosuppressive drugs, hematologic disease, HIV infections, overwhelming TB, recent viral infection, live-virus vaccinations, and malnutrition.[19] If anergy is suspected, control skin tests (*Candida,* mumps, or *Trichophyton*) may be placed in the contralateral arm. If the control test results are positive and the PPD test result is negative, infection with *M. tuberculosis* is less likely. The Centers for Disease Control and Prevention (CDC) changed its

recommendations regarding anergy skin testing in HIV-infected patients with a negative PPD test result. They cite problems with standardization and reproducibility, a low risk for TB associated with a diagnosis of anergy, and the lack of apparent benefit of therapy for latent TB infection in anergic HIV-infected patients. Therefore, the use of anergy testing in conjunction with PPD is no longer routinely recommended in this population or in other patients who are immunocompromised.[50,60,61]

Case 68-1, Question 6: On further questioning, H.G. informs the medical team that he received the bacillus Calmette–Guérin (BCG) vaccine when he was a child in Mexico. What is the BCG vaccine? What effect does the BCG vaccine have on the results of the TST? What other test may be performed in H.G. for detection of *M. tuberculosis* infection?

BCG is a live vaccine derived from an attenuated strain of *M. bovis,* and it is used in many foreign countries with a high prevalence of TB to prevent the disease in persons who are tuberculin negative. Many different BCG vaccines are available worldwide, and they differ with respect to immunogenicity, efficacy, and reactogenicity. Additional factors, such as genetic variability in the vaccinated subjects, the nature of the mycobacteria endemic in different parts of the world, and the use of different doses and immunization schedules, may contribute to the varied degrees of protection provided by the vaccine. The protective effect derived from BCG vaccines in case–control studies ranges from 0% to 80%.[62] Two meta-analyses calculated estimates of the protective efficacy of BCG vaccination for preventing TB. Results from the first meta-analysis indicated a 75% to 86% protective effect against meningeal and miliary TB in children.[63] In the second meta-analysis, the overall protective effect of BCG vaccines was ~50%.[64] Vaccine efficacy was higher in studies in which persons were vaccinated during childhood in contrast with those vaccinated at older ages.[64] Unfortunately, neither study could confirm vaccine efficacy for preventing pulmonary TB.

Prior vaccination with BCG usually results in a false-positive TST finding in patients who are not infected with *M. tuberculosis,* but skin test reactivity does not correlate with protection against TB.[19,62] There is no reliable method of distinguishing TST reactions caused by BCG vaccination from those caused by natural mycobacterial infections.[19,62] Therefore, it is prudent to consider "positive" reactions to 5 TU of PPD in BCG-vaccinated persons as indicating infection with *M. tuberculosis,* especially among persons from countries with a high prevalence of TB.[19] Even though H.G. received the BCG vaccine when he was a child, the results of the PPD skin test should still be considered positive, especially in light of his symptoms.

In general, BCG vaccination is not recommended for routine prophylaxis in the United States because the risk of exposure to TB is relatively low. BCG vaccination should be considered only for very select persons who meet specific criteria and in consultation with a TB expert. BCG vaccination should only be considered for infants or children whose PPD test result is negative and are continually exposed to a highly infectious, untreated patient with active TB or a child who is continually exposed to a person with infectious pulmonary TB caused by *M. tuberculosis* strains resistant to isoniazid and rifampin.[62] BCG vaccination of health care workers should be considered on an individualized basis in settings in which a high prevalence of patients is infected with MDR-TB, transmission of MDR-TB strains to health care workers and subsequent infection are likely, and comprehensive infection control precautions have been unsuccessful.[62] BCG vaccination is contraindicated in pregnancy and in persons who are immunocompromised (eg, HIV infection) or persons who are likely to become immunocompromised (eg, organ transplantation).[62] Adverse reactions to the BCG vaccine vary according to the type, dose, and age of the vaccine. Osteitis, prolonged ulceration at the vaccination site, lupoid reactions, regional suppurative lymphadenitis, disseminated BCG infection, and death have been reported.[62]

An IGRA is preferred over the TST for persons who have received the BCG vaccine.[65] Two IGRAs are currently approved by the FDA as an aid for diagnosing both latent and active *M. tuberculosis*

infection: the QuantiFERON®-TB Gold test (Qiagen) and the T-SPOT®.TB test (Oxford Immunotec). These IGRAs assess response to synthetic peptides that represent specific proteins, early secretory antigenic target-6 (ESAT-6) and culture filtrate protein-10 (CFP-10), that are present in all *M. tuberculosis* strains.[65] In sensitized patients, ESAT-6 and CFP-10 are recognized by T cells and stimulate release of interferon-γ. The QuantiFERON®-TB Gold test measures the interferon-***γ*** concentrations released using an enzyme-linked immunosorbent assay. The T-SPOT®.TB test uses an enzyme-linked immunospot assay (ELISpot) to detect increases in the number of cells that secrete interferon-γ. However, ESAT-6 and CFP-10 are not present in BCG vaccine strains and most nontuberculous mycobacteria; therefore, IGRAs have improved specificity in BCG-vaccinated persons compared with the TST.[65] Results are available within 24 hours compared to 2 to 3 days for TST. IGRAs have essentially replaced TST for all patients because of the high rate of false-negative results and delay in availability of results with TST.

CASE 68-1, QUESTION 7: Should H.G. be tested for HIV infection?

The CDC recommends HIV screening for all patients with TB as well as those persons suspected of having TB disease and contacts of patients with TB.[66] Therefore, H.G. should be tested for HIV. HIV infection is the most important risk factor for progression of latent TB infection to active disease, and progression is more rapid in HIV-infected persons. Unlike other AIDS-related opportunistic infections, CD4 count is not a reliable predictor of increased risk of TB disease in HIV-infected persons.[67] TB may be the first manifestation of HIV infection because patients can have a relatively high CD4 count when TB disease develops.[67]

TREATMENT OF ACTIVE DISEASE

Initial Therapy

Case 68-1, Question 8: H.G.'s HIV test result is negative. How should treatment be initiated in H.G., pending the results of sputum culture and susceptibility testing? Can he transmit *M. tuberculosis* to others during treatment?

There are four basic regimens recommended for the treatment of adult patients with active TB caused by organisms that are known or presumed to be drug susceptible (**Table 68-2**).[34] Because H.G. has not been treated previously for TB, he should be started on the RIPE regimen. However, he has been in close contact with persons with symptoms resembling TB who are from an area (Mexico) with a high prevalence of drug-resistant TB. Therefore, H.G. must be closely monitored for resolution of symptoms, results of repeated sputum smears, and culture and susceptibility results, regardless of the initial treatment regimen. Previous guidelines recommended the addition of ethambutol only if the local prevalence of isoniazid-resistant *M. tuberculosis* is at least 4%.[36,68] In the United States, 9.2% of *M. tuberculosis* isolates recovered from patients with no previous history of TB were resistant to isoniazid in 2019.[11] The prevalence of isoniazid resistance was higher in foreign-born persons (10.2%) compared with U.S.-born persons (6.5%).[11] In patients with a previous history of TB, 14.1% of strains were resistant to isoniazid in 2019, with 15.4% resistance in foreign-born persons versus 9.7% resistance in U.S.-born persons.[11] Because of the relatively high likelihood of TB caused by isoniazid-resistant organisms, four drugs are necessary in the initial 8-week treatment phase.[34]

Table 68-2
Treatment Regimens for Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

	Initial Phase		Continuation Phase			
Regimen	Drugs	Interval and Doses[a] (Minimal Duration)	Drugs	Interval and Doses[a,b] (Minimal Duration)	Range of Total Doses (Minimal Duration)	Comments [b,c]
1	RIF INH PZA EMB	7 days per week for 56 doses (8 weeks) *or* 5 days per week for 40 doses (8 weeks)	RIF INH	7 days per week for 126 doses (18 weeks) *or* 5 days per week for 90 doses (18 weeks)	182–130 (26 weeks)	Preferred regimen for newly diagnosed pulmonary tuberculosis
2	RIF INH PZA EMB	7 days per week for 56 doses (8 weeks) *or* 5 days per week for 40 doses (8 weeks)	RIF INH	Three times weekly for 54 doses (18 weeks)	110–94 (26 weeks)	Preferred alternative regimen in situations where more frequent DOT is a concern
3	RIF INH PZA EMB	Three times weekly for 24 doses (8 weeks)	RIF INH	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)	Use with caution in patients with HIV or cavitary disease. Missed doses may lead to treatment failure, relapse, and/or acquired drug resistance.
4	RIF INH PZA EMB	7 days per week for 14 doses, then twice weekly for 12 doses	RIF INH	Twice weekly for 36 doses (18 weeks)	62 (26 weeks)	Do not use twice-weekly regimens in patients with HIV or smear-positive and/or cavitary disease.

DOT, directly observed therapy; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin.

[a]Drugs may be given 5 days per week with adjustment of the total number of doses when directly observed therapy (DOT) is used. No studies have compared 5 days per week to 7 days per week, but extensive experience supports 5 days per week administration with DOT.

[b]The continuation phase should be extended to 31 weeks for patients with cavitary disease on initial chest radiograph and positive culture results at the end of 2 months of intensive therapy.

[c]Pyridoxine 25 to 50 mg daily is given with isoniazid to decrease the risk of peripheral neuropathy. The dose should be increased to 100 mg daily for patients with peripheral neuropathy.

The initial four-drug regimen should be administered for 8 weeks and may be administered daily for 7 or 5 days/week (regimens 1 and 2), thrice weekly (regimen 3), or daily for the first 2 weeks and then twice weekly for 6 weeks (regimen 4).[34] The preferred administration schedule is daily by DOT. Based on clinical experience, 5 days per week administration is considered to be equivalent to 7 days per week administration and either regimen 1 or 2 may be considered "daily." However, 5-day-a-week administration should always be given by DOT.[34] Thrice-weekly dosing (regimen 3) may be considered in HIV-uninfected patients with noncavitary disease if

daily treatment is not feasible or poorly tolerated. However, thrice-weekly dosing has been associated with higher rates of treatment failure, relapse, and acquired drug resistance.[34] Regimen 4 is generally not recommended owing to lack of high-quality supporting evidence and concern for missed doses resulting in once-weekly dosing, which is inferior. This regimen may be considered if daily- or thrice-weekly DOT is not feasible in patients who are HIV uninfected and at low risk for relapse (drug susceptibility known, noncavitary and/or smear result negative). Drug dosages for these recommended regimens are listed in **Table 68-3**. H.G. should be started on rifampin 600 mg daily, isoniazid 300 mg daily, pyrazinamide 1500 mg daily, and ethambutol 1200 mg daily. He should also receive pyridoxine 25 to 50 mg/day to minimize the risk of developing isoniazid-induced peripheral neuropathy. For patients with peripheral neuropathy, pyridoxine 100 mg daily may be given.[34] If the TB strain is susceptible to both rifampin and isoniazid, ethambutol is not necessary, and the intensive phase may be completed with rifampin, isoniazid, and pyrazinamide.[34]

Table 68-3
Drugs Used in the Treatment of Tuberculosis in Adults and Children

Drug	Dosing (Maximum Dose)	Primary Side Effects	Dose Adjustment in Renal Impairment	Comments
First-Line Agents				
Isoniazid	Adults: 5 mg/kg (300 mg) daily; 15 mg/kg (900 mg) once, twice, or thrice weekly Children: 10–15 mg/kg (300 mg) daily; 20–30 mg/kg (900 mg) once or twice weekly	Increased aminotransferases (asymptomatic), clinical hepatitis, peripheral neuropathy, CNS effects, lupus-like syndrome, hypersensitivity reactions	No	Peripheral neuropathy preventable with pyridoxine 25–50 mg. Hepatitis more common in older patients and alcoholics. Potent inhibitor of CYP2C9, CYP2C19, CYP2E1. ↑ serum level of phenytoin
Rifampin	Adults: 10 mg/kg (600 mg) once daily, twice weekly, or thrice weekly Children: 15–20 mg/kg (600 mg) once daily or thrice weekly	Pruritus, rash, hepatotoxicity, GI (nausea, anorexia, abdominal pain), flulike syndrome, thrombocytopenia, renal failure	No	Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Potent inducer of CYP3A4, CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, and CYP3A5.
Rifabutin	Adults: 5 mg/kg (300 mg) once daily, twice weekly, or thrice weekly Children: unknown; estimated 5 mg/kg	Neutropenia, uveitis, GI symptoms, polyarthralgias, hepatotoxicity, rash	No	Orange-red discoloration of body secretions (sweat, saliva, tears, urine). Weaker inducer of hepatic microsomal enzymes than is rifampin.
Rifapentine	Adults: Active disease, 10–20 mg/kg (600 mg) once weekly during continuation phase; latent infection, 15 mg/kg (900 mg) once weekly Children 2–11 years: 15 mg/kg (900 mg) once weekly	Similar to rifampin	Unknown	Drug interactions due to induction of hepatic microsomal enzymes (see rifampin)
Pyrazinamide	Adults: 40–55 kg: 1 g daily, 2 g twice weekly, 1.5 g thrice weekly; 56–75 kg: 1.5 g daily, 3 g twice weekly, 2.5 g thrice weekly; 76–90 kg: 2 g daily, 4 g twice weekly, 3 g thrice weekly Children: 30–40 mg/kg (2 g) daily; 50 mg/kg (2 g) thrice weekly	Hepatotoxicity, nausea, anorexia, polyarthralgias, rash, hyperuricemia, dermatitis	Yes	Monitor aminotransferases monthly.
Ethambutol	Adults: 40–55 kg: 800 mg daily, 2 g twice weekly, 1.2 g thrice weekly; 56–75 kg: 1.2 g daily, 2.8 g twice weekly, 2 g thrice weekly; 76–90 kg:1.6 g daily, 4 g twice weekly, 2.4 g thrice weekly Children: 15–25 mg/kg (1 g) daily; 50 mg/kg (2.5 g) twice weekly	Optic neuritis, skin rash, drug fever	Yes	Routine vision tests recommended; 50% excreted unchanged in urine
Second-Line Agents				
Cycloserine	Adults: 10–15 mg/kg/day (1 g), usually 500–750 mg/day in 2 divided doses Children: 10–15 mg/kg/day (1 g)	CNS toxicity (psychosis, seizures), headache, tremor, fever, skin rashes	Yes	May exacerbate seizure disorders or mental illness. Some toxicity preventable by pyridoxine (100–200 mg/day). Monitor serum concentrations (peak 20–35 μg/mL desirable).

Drug	Dosing (Maximum Dose)	Primary Side Effects	Dose Adjustment in Renal Impairment	Comments
Ethionamide	Adults: 15–20 mg/kg/day (1 g), usually 500–750 mg/day in one daily dose or 2 divided doses Children: 15–20 mg/kg/day (1 g)	GI effects (metallic taste, nausea, vomiting, anorexia, abdominal pain), hepatotoxicity, neurotoxicity, endocrine effects (alopecia, gynecomastia, impotence, hypothyroidism), difficulty in diabetes management	Yes	Must be given with meals and antacids. Monitor aminotransferases and thyroid-stimulating hormone monthly.
Streptomycin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 20–40 mg/kg/day (1 g)	Vestibular or auditory dysfunction of eighth cranial nerve, renal dysfunction, skin rashes, neuromuscular blockade	Yes	Audiometric and neurologic examinations recommended; 60%–80% excreted unchanged in urine. Monitor renal function.
Amikacin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 15–30 mg/kg/day (1 g)	Ototoxicity, nephrotoxicity	Yes	Less vestibular toxicity than with streptomycin. Monitoring similar to that for streptomycin
Capreomycin	Adults: 15 mg/kg/day (1 g); ≥60 years, 10 mg/kg/day (750 mg) Children: 15–30 mg/kg/day (1 g) as single dose or twice-weekly dose	Nephrotoxicity, ototoxicity	Yes	Monitoring similar to that for streptomycin
p-Aminosalicylic acid (PAS)	Adults: 8–12 g/day in 2–3 doses Children: 200–300 mg/kg/day in 2–4 divided doses	GI intolerance, hepatotoxicity, malabsorption syndrome, hypothyroidism	Yes	Liver enzymes and thyroid function should be monitored.
Levofloxacin	Adults: 500 to 1000 mg/day	Nausea, diarrhea, abdominal pain, anorexia, headache, dizziness, QT prolongation, tendon pain or rupture	Yes	Do not give with divalent or trivalent cations (aluminum, magnesium, iron, etc).
Moxifloxacin	Adults: 400 mg/day	Nausea, diarrhea, abdominal pain, anorexia, headache, dizziness, QT prolongation, tendon pain or rupture	No	See levofloxacin.
Bedaquiline	Adults: 400 mg once daily for 2 weeks, then 200 mg thrice weekly for 22 weeks	Nausea, arthralgias, headache, increased transaminases, hemoptysis, chest pain, anorexia, rash, QT prolongation	No	Take with food. CYP3A4 substrate, avoid concomitant administration with inducers and inhibitors. Increased mortality compared to that of placebo

CNS, central nervous system; CYP, cytochrome P450; GI, gastrointestinal.

Fixed-dose combinations of drugs have been advocated to improve adherence to the prescribed regimen, especially during the critical initial treatment phase. There are two fixed-dose combination preparations available in the United States: Rifamate®, which contains isoniazid 150 mg and rifampin 300 mg/capsule, and Rifater®, which contains isoniazid 50 mg, rifampin 120 mg, and pyrazinamide 300 mg/tablet. These formulations are a means of minimizing inadvertent monotherapy, especially when DOT is not possible, and they may decrease the risk of acquired drug resistance while reducing the number of capsules or tablets that must be ingested each day.[34] Safety and efficacy of a four-drug fixed-dose

combination regimen was compared, with each drug administered separately in patients with pulmonary TB.[69] The combination tablet contained isoniazid 75 mg, rifampin 150 mg, pyrazinamide 400 mg, and ethambutol 275 mg, and two to five tablets were ingested per day based on body weight. The number of patients whose results were culture negative at 18 and 24 months was similar between the treatment groups, in addition to the number of treatment failures, relapses, and death. The four-drug fixed-dose combination was noninferior to each drug administered separately.[69] It should be noted that there was no difference in outcomes based on HIV status, but <7% of the study subjects were HIV positive.[69]

The high risk of transmission of *M. tuberculosis* to other persons mandates that hospitalized persons with suspected or confirmed infectious TB be placed in respiratory isolation until they are determined not to have TB, they are discharged from the hospital, or they are confirmed to be noninfectious.[36] Based on H.G.'s subjective and objective findings, he should be placed in respiratory isolation. H.G.'s symptoms should improve within the first 4 weeks. He would be considered to be noninfectious when he is receiving effective drug therapy, is improving clinically, and has had negative results for three consecutive sputum AFB smears collected on different days.[36] Patients who have responded clinically may be discharged to home despite positive smear results if their household contacts have already been exposed and these contacts are not at increased risk for TB (eg, infants, HIV-positive and immunosuppressed persons). In addition, patients discharged to home with positive smear results must agree not to have contact with other susceptible persons.[36]

Fluoroquinolones as Initial Therapy

Interest in fluoroquinolones for the treatment of TB dates back >30 years, with a report describing the use of ofloxacin in 19 patients with chronic, drug-resistant TB disease.[70] Several fluoroquinolones possess in vitro activity against *M. tuberculosis*, but moxifloxacin is four- to eightfold more potent than is levofloxacin.[71] Moxifloxacin was

compared with ethambutol in the first 2 months of treatment in adults with smear result–positive pulmonary TB.[72] Patients were randomly assigned to receive moxifloxacin 400 mg daily or ethambutol (based on body weight), and all patients received rifampin, isoniazid, and pyrazinamide. Patients receiving moxifloxacin were more likely to have negative sputum culture results at 4 and 6 weeks, but the 2-month conversion rates were equal in each group.[72] In another study, sputum culture conversion at 8 weeks was significantly greater in patients treated with moxifloxacin when compared with ethambutol (80% vs 63%).[73] Culture conversion rates were also significantly higher in the moxifloxacin group at weeks 1, 2, 3, and 4, and the median time to consistently negative culture results was 35.0 days in the moxifloxacin group and 48.5 days in the ethambutol group.[73]

Moxifloxacin has been compared with isoniazid during the intensive phase of treatment of pulmonary TB.[74] Patients were randomly assigned to receive moxifloxacin 400 mg or isoniazid 300 mg daily, and all patients received rifampin, pyrazinamide, and ethambutol.[74] After 8 weeks, negative sputum culture results were observed in 60.4% of the patients in the moxifloxacin group and 54.9% of patients in the isoniazid group, but this difference was not statistically significant.[74]

Despite the reported efficacy of fluoroquinolones in the treatment of TB, clinicians must be cognizant of the potential development of resistance to this important drug class. Fluoroquinolone resistance in *M. tuberculosis* has been described, occurring more frequently in multidrug-resistant isolates.[9,75] Globally, resistance to any fluoroquinolone was 20.1% in MDR-TB cases in 2019.[9] Fluoroquinolones are widely used in the United States, and outpatient use for infections other than TB could be a potential risk factor for TB resistance in a patient who becomes infected with *M. tuberculosis.* In a study evaluating risk factors for fluoroquinolone-resistant *M. tuberculosis,* investigators identified newly diagnosed patients with culture-confirmed TB in a Medicaid population.[76] Of the 640 patients evaluated, 116 (18%) patients had fluoroquinolone exposure in the 12 months before diagnosis with TB, and 16 (2.5%) patients were infected with *M. tuberculosis* strains that were

fluoroquinolone resistant.[76] The study found that receipt of a fluoroquinolone for >10 days, occurring >60 days before diagnosis of TB, was associated with the highest risk for fluoroquinolone resistance.[76] Therefore, judicious use of fluoroquinolones, especially in patients at risk for TB infection, is mandatory to maintain the utility of fluoroquinolones in the treatment of TB.

Susceptibility Testing

Drug susceptibility testing is essential to ensure proper treatment of patients with active disease and should be performed on the initial isolate of *M. tuberculosis* from all patients.[19] Susceptibility testing should also be performed if culture results remain positive after 3 months of therapy or if negative culture results become positive after a period of time. Traditionally, susceptibility testing is performed by growing the organism on solid or in liquid media containing the drug. The agar proportion method allows for quantitation of the proportion of organisms that are resistant to a given drug, which is expressed as a percentage of the total organism population tested.[19] A drug will not be useful for therapy if ≥1% of the total population is resistant to the drug. Unfortunately, susceptibility results may not be available for several weeks because of the slow growth of the organism and the need to isolate the pathogen before susceptibility testing can be performed.[19]

To expedite susceptibility reporting, molecular drug resistance tests have been developed to detect mutations in the chromosomal sequence encoding for resistance to a specific drug directly on clinical specimens without the need for growth on culture.[56],[57] For example, mutations in the *rpoB* gene block the activity of rifampin by preventing the drug from binding to RNA polymerase. Approximately 95% of rifampin-resistant *M. tuberculosis* carry this mutation, and treatment failures have been associated with the presence of *rpoB* mutations.[77],[78] The molecular drug resistance test amplifies the target genetic sequence using polymerase chain reaction, and a second assay, such as DNA sequencing and hybridization assays, is

used to determine whether the sequence contains a mutation associated with drug resistance. If a mutation is detected, the organism is considered to be drug resistant, but the organism is presumed to be drug susceptible if a mutation is not detected. Molecular tests can reliably detect the presence of known mutations within 1 to 2 days, which may result in earlier initiation of effective therapy, shorter durations of infectivity, and reduced spread of TB. However, these molecular drug resistance tests can only detect a specific set of known mutations and cannot identify novel mutations conferring resistance.[57] Therefore, traditional susceptibility testing continues to play an important role in confirming results of molecular testing.[56]

The Xpert® MTB/RIF assay (Cepheid) is an automated molecular-based test that uses nested real-time polymerase chain reaction, allowing for simultaneous detection of *M. tuberculosis* and rifampin resistance. The test is approved for diagnostic testing of raw sputum samples, and results are available within 2 hours.[56] Sensitivity was 95% to 98.2% in AFB culture or smear specimens that returned positive results, but performance was correlated with bacterial load because sensitivity was only 55% to 72.5% in smear specimens with negative results.[79],[80] Specificity was 94% to 99.2% in patients with negative culture results.[79],[80] A recent, large meta-analysis demonstrated pooled sensitivity and specificity of 85% and 98%, respectively, for the Xpert® MTB/RIF assay with a sensitivity of 98% in AFB smear-positive sample results and 67% in AFB smear-negative, culture-positive sample results.[81] Sensitivity was lower in patients with HIV infection (81%) compared to patients without HIV infection (88%), with no difference in specificity (98%).[81] The sensitivity and specificity of the Xpert® MTB/RIF test for detection of rifampin resistance was 96% and 98%, respectively.[81] The Xpert® MTB/RIF Ultra assay demonstrated higher sensitivity and lower specificity for detection of TB with similar sensitivity and specificity for detection of rifampin resistance compared to the Xpert® MTB/RIF assay.[81]

Case 68-1, Question 9: Is H.G. a risk to the community and does anyone need to know?

Yes! Each case of active TB disease must be reported to the local, state, or both public health departments.[19,36,82] This not only results in optimal therapy by monitoring adherence to therapy but it also ensures that contact and source-case investigations will be performed. All individuals who have been in close contact with H.G. should be evaluated for latent TB infection or active disease. Considering their close contact with H.G. and his coworkers, his family members should be evaluated. Reporting of cases also permits record-keeping and surveillance to determine whether public health TB control efforts are achieving their goal of preventing the spread of TB.[36,82]

Continuation Therapy

REGIMENS

Case 68-1, Question 10: Four weeks later, H.G.'s initial sputum culture results were reported to be positive for *M. tuberculosis*. Drug susceptibility testing to rifampin and isoniazid revealed susceptibility to both agents. What drug regimen should be used for continued treatment of H.G.? How long should treatment be continued? What microbiologic testing should be performed during treatment?

Successful treatment of uncomplicated TB can be achieved in 6 months (26 weeks) if the RIPE regimen is used for the first 2 months (8 weeks) and if patient adherence to the regimen and organism susceptibility can be assured.[34] Therefore, after 8 weeks of DOT with the RIPE regimen, H.G.'s regimen may be streamlined to rifampin and isoniazid daily (5 or 7 days per week) or twice- or thrice-weekly administration under continued DOT for an additional 18 weeks (Table 68-2). Three times a week is preferred over twice-weekly administration because of concerns for missed doses resulting in an inferior once-weekly regimen. Once-weekly treatment with isoniazid

900 mg and rifapentine 600 mg is generally not recommended but may be considered only in HIV-uninfected patients without cavitary lesions and negative sputum culture results at the end of the intensive phase.[34]

The effectiveness of a primarily twice-weekly treatment regimen has been demonstrated in both pulmonary and extrapulmonary TB.[83] The regimen consisted of rifampin 600 mg, isoniazid 300 mg, pyrazinamide 1.5 to 2.5 g, and streptomycin 750 to 1000 mg intramuscularly daily for 2 weeks, followed by the same drugs twice weekly for an additional 6 weeks. The regimen was then reduced to isoniazid and rifampin twice weekly for the remaining 16 weeks (4 months). At 3 months, 75% of patients had negative sputum culture results, and all patients returned culture-negative results at 20 weeks.[83] Relapse occurred in two patients and only minor adverse effects were reported. An important feature is that this regimen is highly cost-effective primarily because of the lowest number of patient–health care worker encounters (62 directly observed doses). However, adherence must be ensured for twice-weekly administration.

If pyrazinamide cannot be included in the initial regimen, therapy should be initiated with rifampin, isoniazid, and ethambutol for the first 8 weeks. Therapy should be continued with rifampin and isoniazid for 7 months (31 weeks) given either daily or thrice weekly.[34]

Daily administration of rifampin 600 mg and isoniazid 300 mg is preferred for continuation therapy for H.G.; however, he is HIV negative and chest radiography does not demonstrate cavitary lesions. Thus, thrice-weekly dosing of rifampin 600 mg and isoniazid 900 mg could be considered for H.G. because this approach requires fewer doses and may result in substantial cost savings.[34] However, negative AFB culture results must be documented at the end of the 8-week intensive phase. Relapse rates for the twice- and thrice-weekly rifampin and isoniazid continuation regimens are significantly lower than is the once-weekly regimen of isoniazid 900 mg and rifapentine 600 mg.[84],[85] Five characteristics were associated with increased relapse risk in the isoniazid/rifapentine group: sputum

culture result positive at 2 months; cavitation on chest radiograph; underweight; bilateral pulmonary involvement; and non-Hispanic Caucasian race.[85] A potential explanation for these results is the high protein binding of rifapentine (98%). A study evaluated the safety and tolerability of rifapentine 600, 900, and 1200 mg once weekly (with isoniazid 15 mg/kg) in 150 HIV-negative patients.[86] A trend toward more adverse events was observed in the 1200-mg treatment arm (P = .051), but the 900-mg dose was well tolerated.[86] However, relapse rates for the higher dose weekly rifapentine regimens with isoniazid are unknown. A subsequent study demonstrated that low plasma concentrations of isoniazid were associated with failure or relapse with once-weekly isoniazid and rifapentine.[87] Two patients who relapsed with *M. tuberculosis* monoresistant to rifamycin had very low isoniazid concentrations. Rapid acetylation status was a risk factor in those patients who failed or relapsed.[87] However, rifamycin pharmacokinetics did not influence patient outcomes.[87]

Treatment with rifampin and isoniazid should be continued for a minimum total duration of 26 weeks. A full course of therapy can be more accurately determined by the total number of doses ingested, not solely by the duration of therapy.[34] Thus, 26 weeks is the minimum duration of treatment and accurately indicates the amount of time the drugs are given only if there are no interruptions in drug administration.[34] During treatment of pulmonary TB, sputum samples for AFB smear and culture should be obtained at least monthly until two consecutive samples return culture-negative results. If the patient has AFB-positive smear results at diagnosis, as in the case of H.G., follow-up samples for AFB smears may be obtained every 2 weeks until two consecutive sample results are negative.[34] On occasion, AFB culture results may be negative despite positive AFB smear results, but the positive smears likely contain dead organisms and does not represent treatment failure. Duration of the continuation phase is dependent on the microbiologic status of the patient at the end of the intensive phase. If AFB culture results remain positive after the intensive phase, the continuation phase should be continued for 7 months (31 weeks).[34]

Pyridoxine 25 to 50 mg/day should be continued throughout the treatment period. If H.G. is symptomatic or has smear- or culture-positive results after 3 months of therapy, he should be reevaluated for possible nonadherence with his therapy, malabsorption of the drugs, or infection with drug-resistant organisms. Evaluation should include a second culture and a second susceptibility test, consideration of DOT (if not already instituted), and consultation with experts in the treatment of TB.[36]

Case 68-1, Question 11: H.G. is concerned about the long duration required for treatment of his infection. He asks whether there is any way to shorten the length of treatment. Are there any effective treatment regimens that may be administered for <26 weeks?

Treatment of active TB for 26 weeks is a challenge to ensure that patients adhere to the prescribed regimen for the total duration of therapy. Shorter course treatment regimens, if efficacious, could be helpful in improving adherence rates, decreasing treatment costs, and reducing adverse events. Three published studies evaluated the treatment of drug-susceptible TB for a total duration of 4 months using modified regimens that included a fluoroquinolone (moxifloxacin or gatifloxacin).[88–90] The control regimen was the same in each study and consisted of 8 weeks of RIPE followed by rifampin and isoniazid for 18 weeks. In all three studies, unfavorable outcomes and culture-confirmed relapse/recurrence were more common in patients receiving the short-course regimens; therefore, noninferiority was not demonstrated for any of the 4-month regimens.[88–90] Based on these studies, H.G. should receive 26 weeks of therapy, and every effort should be made to ensure adherence to the treatment regimen.

Directly Observed Therapy

Case 68-1, Question 12: What is DOT, and why is it important for H.G. to be treated using DOT?

DOT is the practice of a health care provider or other responsible person observing as the patient ingests *and* swallows the TB medications. DOT is the preferred core management strategy for *all* patients with TB.[34–37] The purpose of DOT is to ensure adherence to TB therapy. DOT not only ensures completion of therapy but it may also reduce the risk of developing drug resistance. By improving these two factors, it also reduces the risk of transmission of TB to the community. DOT can be administered with daily or twice- and thrice-weekly regimens. It can be administered to patients in the office or clinic setting, or it can be given at the patient's home, school, or work.[34],[68] Often, enablers or incentives, such as food, clothing, or transportation, are used to improve adherence to DOT. A comprehensive review of DOT-related articles found that the completion rate of TB therapy exceeds 90% when DOT is used along with enablers.[37],[91] A study found that patients with positive culture results treated for active pulmonary TB with DOT had significantly higher cure rates (97.8% vs 88.6%; $P > .002$) and lower TB-related mortality (0% vs 5.5%; $P = .002$) compared with patients treated using self-administered therapy.[92] Although DOT is recommended for all patients, public health departments may not be able to provide DOT for all patients because of the associated costs. The initial cost of DOT is greater than self-administered therapy; however, when costs of relapse and failure are included in a cost-effectiveness analysis, DOT is significantly less expensive than is self-administered therapy.[93] When drug resistance develops (in those instances in which DOT is not used), the cost of salvage therapy increases to $180,000.00 per patient.[94] It is, therefore, widely accepted that patients with TB should receive DOT.[93],[95]

Multiple-Drug Therapy

Case 68-1, Question 13: Why are multiple drugs recommended for treatment of active TB disease? What is the role of each drug in the treatment of active TB?

The key to treating active TB disease is multiple-drug therapy for a period sufficient to kill the organisms and to prevent development of resistant strains of *M. tuberculosis.* Most cavitary lesions contain a concentration of 10^9 to 10^{12} organisms, and the frequency of mutations that confer resistance to a single drug is ~10^{-6} for isoniazid and streptomycin, 10^{-8} for rifampin, and 10^{-5} for ethambutol. Considering the inoculum of organisms involved, patients with active TB disease likely harbor organisms with random mutations that confer drug resistance to a given drug. If a single drug is given, it would reduce the number of drug-susceptible organisms but allow the drug-resistant organisms to replicate. By using multiple-drug therapy, the likelihood of encountering organisms with mutations to multiple drugs is reduced. For example, the frequency of concurrent mutations to isoniazid and rifampin would be 10^{-14} (10^{-6} for isoniazid and 10^{-8} for rifampin), making simultaneous resistance to both drugs an unlikely event in an untreated patient. Therefore, monotherapy should never be used in the treatment of active TB disease.[34],[94]

Multiple-drug therapy also serves to sterilize the sputum and lesions as quickly as possible. The drugs available for the treatment of TB vary in their ability to accomplish this task.[34] Drugs effective against tubercle bacilli can be divided into first-line and second-line agents (Table 68-3). The foundation of treatment should be with first-line agents, such as RIPE. Of the various agents, isoniazid has the most bactericidal activity versus rapidly multiplying *M. tuberculosis* during the initial phase of therapy (early bactericidal activity), followed by ethambutol, rifampin, and streptomycin.[96–98] Drugs that have potent early bactericidal activity more rapidly decrease the infectiousness of the patient and reduce the likelihood of developing resistance. Pyrazinamide has weak early bactericidal activity during the first 2 weeks of therapy and is less effective in preventing emergence of drug resistance than are isoniazid, rifampin, and ethambutol.[96],[99] Therefore, pyrazinamide should not be combined with only one other agent when treating active TB disease. Rifampin also has activity against intracellular organisms that are usually dormant but undergo periods of active growth. This ability to

penetrate and destroy the persistent intracellular organisms makes rifampin extremely valuable in short-course chemotherapy regimens.[100]

Pyrazinamide is most effective against tubercle bacilli in the acidic environment within the macrophage or areas of tissue necrosis. In addition, it is most effective in sterilizing lesions when used in the first 2 months of treatment, but it does not offer substantial sterilizing activity after 2 months. Pyrazinamide should be considered an essential component of short-course regimens.[34,68]

Ethambutol is bacteriostatic at low doses, but bactericidal at higher doses. It is moderately effective against the fast-growing bacilli. It has little sterilizing activity and is primarily used to prevent the emergence of drug-resistant organisms.[68]

Other drugs used in the treatment of TB (bedaquiline, capreomycin, amikacin, cycloserine, ethionamide, *p*-aminosalicylic acid) are usually reserved for cases involving drug-resistant organisms, treatment failures, drug toxicity, or patient intolerance to the other agents. Their use is discussed later in the chapter.

Monitoring Drug Therapy

Case 68-1, Question 14: What subjective and objective findings should be followed to ensure therapeutic efficacy and to minimize drug toxicity? Should H.G. be followed up closely after completion of his treatment regimen?

H.G. should be questioned about the occurrence of adverse reactions associated with his therapy (see Table 68-3). Specifically, he should be asked about anorexia, nausea, vomiting, or abdominal pain, which may be an indication of possible hepatitis secondary to isoniazid, rifampin, or pyrazinamide. He should be questioned about numbness and tingling in his extremities; however, isoniazid-induced peripheral neuropathy should not be a problem in H.G. because he is also taking pyridoxine, which should prevent this adverse effect. H.G. also should be examined for, and questioned about, petechiae or bruises, because thrombocytopenia occurs occasionally with

rifampin therapy. This effect purportedly occurs more frequently with intermittent rifampin therapy, but it is rare at the currently recommended intermittent rifampin dose of 10 mg/kg/day (≈600 mg).[68]

In a study comparing 6- versus 9-month antituberculosis therapies of mostly isoniazid and rifampin, the incidence of side effects was similar between the two groups. Adverse effects occurred in 7.7% of patients in the 6-month arm compared with 6.4% in the 9-month arm, which was not statistically significant.[101] Hepatic abnormalities occurred in 1.6% of patients in the 6-month regimen and 1.2% in the 9-month regimen (not statistically significant). Hematologic events were rare at 0.2% and 0.0% in the 6- and 9-month groups, respectively. Other reported effects, gastrointestinal (GI) problems, rash, and arthralgias were minor and infrequent in both regimens.[101]

OBJECTIVE SIGNS

A pretreatment complete blood count, platelet count, blood urea nitrogen, hepatic enzymes (serum aminotransferases), bilirubin, and serum uric acid should be evaluated. Baseline visual examination should also be considered for patients receiving ethambutol. These tests are performed to detect any abnormality that may complicate or necessitate modification of the prescribed regimen. These tests should be repeated if the patient experiences any evidence of drug toxicity or has abnormalities at baseline.[34,68]

H.G. is 35 years old and at increased risk for development of drug-induced hepatotoxicity. Isoniazid can cause asymptomatic increases in serum transaminases as well as overt hepatitis.[34] Pyrazinamide has also been associated with hepatotoxicity, but the incidence is less common at doses of ≤25 mg/kg/day. Transient asymptomatic hyperbilirubinemia and cholestatic hepatitis can occur in patients receiving rifampin.[34] Therefore, it is important that H.G. be educated about possible symptoms of hepatotoxicity, primarily nausea, vomiting, abdominal pain, anorexia, and jaundice. Monthly serum liver function tests (LFTs) are no longer recommended because they are costly, and transient, asymptomatic elevations in LFTs may

occur, which could result in unnecessary discontinuation of optimal therapy. The CDC recommends that medical personnel question patients about symptoms once monthly.[68]

Sputum cultures and smears for AFB should be ordered every 2 to 4 weeks initially and then monthly after the sputum culture results become negative. With appropriate therapy, sputum culture results should become negative in >85% of patients after 2 months. Radiologic examination (chest radiographs) is not as important as sputum examination, but it may be useful at the completion of therapy to serve as a comparison for any future films.

Patients whose culture results are positive at 2 months need to be carefully reexamined. Drug susceptibility testing should be performed to rule out acquired drug resistance, and special attention should be given to drug adherence (ie, DOT should be used). If drug resistance is demonstrated, the regimen should be modified as needed. Sputum cultures should also be obtained monthly until result negativity is achieved.[68]

As was the case for H.G., weight loss and nutritional depletion are common in patients with active TB disease. In a large TB treatment study, 7.1% of patients experienced relapse, with relapse greatest in patients who were underweight at diagnosis or with a body mass index <18.5 kg/m^2.[102] In patients underweight at diagnosis (defined as ≥10% below ideal body weight), weight gain of ≤5% between diagnosis and completion of 2 months of therapy was independently associated with relapse.[102] In addition, the relapse rate was 50.5% in underweight patients with a cavitary lesion on chest radiograph, positive sputum culture results after 2 months of therapy, and a ≤5% weight gain in the first 2 months of therapy.[102] Therefore, it may be prudent to monitor H.G.'s body weight during the initial 2 months of therapy, and he may need to receive more intensive therapy or a longer duration of therapy.

Routine follow-up usually is not required after the successful completion of chemotherapy with isoniazid and rifampin. It may be prudent, however, to reexamine the patient 6 months after completion of therapy or at the first sign of any symptoms suggestive of active TB. This is especially important in patients who were slow

to respond to therapy or who have significant radiologic findings at completion of therapy. These recommendations are only for those patients with organisms fully susceptible to the medications being used.[68]

Patients whose culture results are negative but have radiographic abnormalities consistent with TB should have an induced sputum or bronchoscopy performed to establish a microbiologic diagnosis and be monitored radiographically. Patients with extrapulmonary TB should be evaluated according to the site of involvement.[34,68]

Treatment Failure

Case 68-1, Question 15: If H.G. does not respond to his currently prescribed treatment regimen, should one additional drug be added to his regimen?

No! Adding a single drug to a failing regimen is the most common and devastating prescribing error in TB therapy. This practice is essentially monotherapy because the assumption is that the organisms are resistant to the medications currently being used. Resistance to the new drug will eventually develop, further reducing the patient's chance of cure. At least two, and preferably three, new drugs to which susceptibility can be inferred should be added to lessen the probability of further acquired drug resistance. Empiric retreatment regimens may include a fluoroquinolone, bedaquiline, an injectable agent (eg, streptomycin, amikacin, or capreomycin), and an additional oral agent (eg, *p*-aminosalicylic acid, cycloserine, or ethionamide).[34] New drug susceptibility testing should be performed and treatment adjusted accordingly.[34,94]

TREATMENT OF LATENT TUBERCULOSIS INFECTION

CASE 68-2

QUESTION 1: J.G., the 32-year-old wife of H.G., and their children are tested to determine whether they have been infected with *M. tuberculosis.* For J.G., the induration from 5 TU of PPD was 12 mm, a result that is reported as positive. J.G. states that she has never received the BCG vaccine. The PPD results for the children were negative. J.G. does not have any clinical symptoms or radiographic findings suggestive of active TB at this time, and her current weight is 132.28 pounds (60 kg).

Is she at risk for developing active disease? What are the current recommendations for drug therapy for persons with latent TB infection? Should J.G. receive treatment?

Because J.G. is a household contact of a person with active TB disease and has a positive TST finding, she is at great risk for developing active disease.[23],[24],[50],[51] During the first year after infection from the index case, a household contact's risk of developing active disease is 2% to 4%, and contacts with a positive TST finding are at the greatest risk.[68] As with active disease, the TST is usually performed to detect the presence of latent TB infection. However, for contact investigation, studies have demonstrated that IGRAs are a more accurate indicator of the presence of latent TB infection than is TST.[103],[104] Therefore, many health departments in the United States have adopted IGRAs as screening tests for contact investigations.[105] The majority of people with a negative IGRA result after exposure to a person with active TB disease do not have TB infection; however, the immune reaction to TB can take several weeks to develop, so the IGRA should be repeated 8 to 12 weeks after the last exposure to rule out infection.[24],[105] TST is preferred for screening children younger than 5 years old.[24]

Treatment of latent TB infection is effective in preventing active TB disease in patients with a positive TST or IGRA result and in those at risk for reactivation of active TB; therefore, it is *strongly* recommended.[23],[24] Treatment decreases the population of tubercle bacilli and reduces future morbidity from TB in the groups at high risk for developing active disease. Because J.G. is infected with *M.*

tuberculosis but does not currently have active TB disease, she should be treated for latent TB infection.

There are four approved regimens for the treatment of latent TB.[23],[24] Isoniazid monotherapy prevents active TB in 90% of patients who complete a 9-month regimen compared to 60% to 80% of patients who complete a 6-month regimen.[106] Therefore, isoniazid 300 mg daily or 900 mg twice weekly for 9 months is preferred. The twice-weekly regimen should be administered by DOT to ensure patient adherence.[20] A 6-month regimen is an acceptable alternative in patients who cannot complete 9 months of therapy.[23] The benefits of treating latent TB infection outweigh the risks of isoniazid-induced hepatitis because all persons infected with TB are at risk for developing active disease throughout their lifetime. All patients receiving isoniazid should receive pyridoxine 25 mg/day to minimize the risk of peripheral neuropathy.

Unfortunately, patient adherence to these isoniazid regimens is very poor. In a population of patients beginning isoniazid treatment for latent TB, only 64% of patients completed at least 6 months of therapy.[107] Younger age, Hispanic ethnicity, and non-U.S. country of birth were associated with greater likelihood of completing therapy.[107] Lower completion rates were associated with homelessness, excess alcohol intake, and experiencing an adverse event.[107] In another study, 52.7% of patients receiving treatment for latent TB infection failed to complete the prescribed course of therapy.[108] More than 93% of these patients were receiving isoniazid. Risk factors for failing to complete therapy included receipt of a 9-month isoniazid regimen, residence in a congregate setting (nursing home, shelter, jail), injection drug use, and employment at a health care facility.[108] In addition, this study reported that employees at health care facilities were more likely to decline treatment for latent TB infection.[108]

Because of concerns for isoniazid toxicity and abysmal adherence rates, shorter rifampin-based regimens may be utilized. Daily isoniazid plus rifampin for 3 months and daily rifampin monotherapy for 4 months are acceptable alternatives to isoniazid therapy.[23],[24],[106] For the patients randomly assigned to receive daily rifampin for 4 months, 91% took 80% of the doses, and 86% took >90% of the

doses at 20 weeks.[109] For the patients randomly assigned to receive daily isoniazid for 9 months, 76% took 80% of the doses, and only 62% took >90% of the doses at 43 weeks.[109] Discontinuation of therapy because of adverse events was more common in the isoniazid group (14%) versus the rifampin group (3%).[109] Another study reported significantly fewer grade 3 to 4 adverse events and hepatitis and significantly higher treatment completion rates with 4 months of rifampin compared with 9 months of isoniazid.[110] Rifampin for 4 months is an effective, safe, and cost-effective strategy to consider when treating latent TB infection in selected populations of patients.[109–113]

An attractive alternative for the treatment of latent TB infection is the combination of isoniazid and rifapentine administered once weekly for 12 weeks.[23],[24] In one study, patients received either isoniazid 15 to 25 mg/kg (maximal dose 900 mg) plus rifapentine 900 mg (with adjustments for patients weighing <50 kg) once weekly for 12 weeks by DOT or isoniazid 5 mg/kg (maximal dose 300 mg) once daily for 9 months.[114] Completion of therapy was significantly higher in the isoniazid/rifapentine group (82% vs 69%; $P > .001$). Overall, TB developed in 7 of 3986 patients receiving isoniazid/rifapentine and 15 of 3745 patients receiving isoniazid (hazard ratio 0.38 for the combination; 95% CI 0.15–0.99; $P = .05$).[114] Hepatotoxicity was higher in the isoniazid group (2.7% vs 0.4%; $P > .001$), whereas hypersensitivity reactions were higher in the combination group (3.8% vs 0.5%; $P > .001$). Permanent drug discontinuation for any reason was higher in the isoniazid group (31.0% vs 17.9%; $P > .001$), but permanent drug discontinuation owing to an adverse event was higher in the combination group (4.9% vs 3.7%; $P = .009$).[114] This combination is recommended as an equal alternative to daily isoniazid for 9 months in patients ages 12 years and older with a greater risk of developing active TB disease.[115] These patients include those with recent exposure to a person with active TB, conversion of the TST or IGRA result from negative to positive, or radiographic evidence of healed pulmonary TB. Isoniazid/rifapentine may also be considered in patients unlikely to complete 9 months of isoniazid or in a setting where the combination offers practical

advantages (eg, correctional facilities, homeless shelters). The combination is not recommended in females who are pregnant or who expect to become pregnant during treatment.

J.G. should be placed on isoniazid 300 mg/day or 900 mg twice weekly for at least 6 months and preferably up to 9 months, rifampin 600 mg for 4 months, or isoniazid 900 mg plus rifapentine 900 mg weekly for 12 weeks.[23],[24],[115] She should be educated and questioned frequently about the clinical symptoms of hepatitis. Pretreatment serum aminotransferases and bilirubin should be assessed to rule out preexisting liver disease. The American Thoracic Society and the CDC do not recommend routine monitoring of LFTs unless symptoms suggest hepatotoxicity.[68]

ADVERSE DRUG EVENTS

Isoniazid

HEPATOTOXICITY

Case 68-2, Question 2: J.G. is started on daily isoniazid. After 2 months of therapy, she presents to the clinic with nausea, vomiting, and abdominal pain. LFTs were ordered, and her aspartate aminotransferase (AST) was 150 IU/L. Discuss the presentation, prognosis, and mechanism of isoniazid-induced hepatitis. What are the risk factors for developing hepatitis? Should isoniazid be discontinued to prevent further liver damage?

Approximately 10% to 20% of patients treated with isoniazid alone for latent TB infection will develop elevated serum aminotransferases, which are generally transient and asymptomatic.[34],[116] Most patients with mild, subclinical hepatic damage do not progress to overt hepatitis and recover completely even while continuing isoniazid. In contrast, continuation of isoniazid in patients with symptoms of hepatitis increases the risk of mortality compared with immediate discontinuation.[34] The risk of death from

TB, however, is estimated to be 11 times higher than is the risk of death from isoniazid hepatotoxicity.[117]

Isoniazid-induced hepatotoxicity generally occurs within weeks to months of initiating therapy; 60% of cases occur in the first 3 months and 80% occur in the first 6 months.[116] Constitutional symptoms may be seen early and may last from days to months. Nausea, vomiting, and abdominal pain are seen in 50% to 75% of patients with severe hepatotoxicity.[116] Jaundice, dark urine, and clay-colored stools may also be seen. Recovery may take weeks after discontinuing isoniazid therapy. Development of isoniazid hepatotoxicity has been linked to several factors, including acetylator phenotype, age, daily alcohol consumption, and concurrent rifampin use. In addition, females may be at higher risk for death, especially during the postpartum period.[117]

The mechanisms responsible for isoniazid hepatotoxicity remain unclear. Previously, it was thought that rapid acetylators had a greater risk for isoniazid hepatotoxicity than do slow acetylators. Rapid acetylators of isoniazid form monoacetylhydrazine, a compound that can cause liver damage, more rapidly than do slow acetylators.[118] Rapid acetylators, however, would eliminate monoacetylhydrazine at a faster rate, and this should equalize the risk of toxicity between slow and fast acetylators.[119] One study demonstrated a different incidence of hepatitis between Asian males and females. Because both groups were fast acetylators, this study suggests that hepatitis is associated with factors other than acetylator phenotype.[120] Some evidence supports the theory that isoniazid-induced hepatitis is a hypersensitivity reaction; however, many patients tolerate isoniazid on rechallenge, discounting this theory.[121,122]

Age and concurrent daily alcohol ingestion are the most consistent risk factors for isoniazid hepatitis.[68] Progressive liver damage is rare in persons younger than age 20 years. It occurs in ~0.3% of persons between ages 20 and 34 years, 1.2% of those between ages 35 and 49 years, and 2.3% of persons older than age 50 years.[68] One prospective cohort study, however, demonstrated a low incidence of isoniazid hepatitis. Of 11,141 patients receiving isoniazid alone for

the treatment of latent TB infection, only 11 (0.1% of those starting and 0.15% of those completing therapy) developed clinical hepatitis.[123] Previous studies suggested a higher incidence of clinical hepatitis in patients receiving isoniazid alone, and a meta-analysis of six studies estimated the rate to be 0.6%.[34] However, severe hepatotoxicity may occur with isoniazid treatment of latent TB infection. The CDC reported 17 severe hepatic adverse events with isoniazid in 15 adults and 2 children (ages 11 and 14 years).[124] Five patients, including one child, underwent liver transplantation, and five adults died (including one patient who underwent liver transplant).

High-risk patients should be followed up with routine monitoring of LFTs. These patients include those who consume alcohol daily, persons older than age 35 years, those taking other hepatotoxic drugs, those with preexisting liver disease, IV drug users, Black and Hispanic females, and all postpartum females. In these high-risk patients, isoniazid should be discontinued if the AST level exceeds three to five times the upper limit of the normal value.[68] Because J.G. is experiencing nausea, vomiting, and abdominal pain and her AST is greater than three times the upper range of the normal value, isoniazid should be discontinued temporarily until the AST returns to normal. At that time, isoniazid should be resumed, and her LFTs rechecked. If the AST increases again, the drug should be discontinued, and J.G. should be followed up frequently for development of active TB.

CASE 68-3

Question 1: C.M., a 176.37-pound (80-kg), 35-year-old female, is being treated for active TB disease with rifampin 900 mg and isoniazid 1200 mg twice weekly.

Is 1200 mg of isoniazid twice weekly an appropriate dose for a 176.37-pound (80-kg) patient? What isoniazid side effects, other than hepatotoxicity, should be anticipated?

The usual twice-weekly isoniazid dose is 15 mg/kg, with a maximal dose of 900 mg. Even though she weighs 176.37 pounds (80 kg), C.M. should be receiving no more than 900 mg rather than 1200 mg

of isoniazid twice weekly. Although high doses or increased serum concentrations have not been linked with hepatitis, elevated serum isoniazid concentrations have been associated with increased central nervous system (CNS) events, ranging from somnolence to psychosis and seizure. GI side effects are also more commonly observed at doses >20 mg/kg.

PERIPHERAL NEUROPATHY

Although uncommon at the recommended daily and intermittent doses, isoniazid can cause peripheral neuropathy by interfering with pyridoxine (vitamin B_6) metabolism.[33,50] As many as 20% of patients may experience this problem with isoniazid doses >6 mg/kg/day. Numbness or tingling in the feet or hands is the most common neuropathic symptom. In patients with medical conditions in which neuropathy is common, including diabetes mellitus, alcoholism, HIV infection, malnutrition, and renal failure, supplemental pyridoxine 25 to 50 mg/day should be given with isoniazid.[34,50] Females who are pregnant or breast-feeding and persons with seizure disorders should also receive supplemental pyridoxine with isoniazid.[50]

ALLERGIC AND OTHER REACTIONS

Allergic reactions consisting of arthralgias, skin rash, swelling of the tongue, and fever have also been reported. Isoniazid has been associated with arthritic symptoms and systemic lupus erythematosus; ~20% of patients receiving isoniazid develop antinuclear antibodies.[34] Other less common reactions reported with isoniazid are dry mouth, epigastric distress, CNS stimulation and depression, psychoses, hemolytic anemia, pyridoxine-responsive anemia, and agranulocytosis.[121]

DRUG INTERACTIONS

Isoniazid is a relatively potent inhibitor of several cytochrome P450 ([CYP] 2C9, CYP2C19, CYP2E1) isoenzymes, but has minimal effects on CYP3A.[34] Isoniazid inhibits the hepatic metabolism of phenytoin and carbamazepine, resulting in increased plasma

concentrations of these drugs. Patients receiving either of these two drugs with isoniazid should be observed for signs of phenytoin or carbamazepine toxicity, such as nystagmus, ataxia, headache, nausea, or drowsiness. Plasma phenytoin and carbamazepine concentrations should be monitored periodically so that the doses can be adjusted if necessary. Carbamazepine also may induce isoniazid hepatitis by inducing its metabolism to toxic metabolites.[125] In addition, isoniazid inhibits the metabolism of diazepam and triazolam. It is important to note that rifampin has the exact opposite effect on hepatic metabolism. Rifampin is a stronger inducer than isoniazid is an inhibitor, as documented by the fact that isoniazid–rifampin combination therapy induces the metabolism of diazepam, phenytoin, and other agents metabolized by the CYP system.[126]

Rifampin

FLULIKE SYNDROME

A flulike syndrome has been reported in 1% of patients receiving intermittent rifampin administration. This syndrome is rarely seen with usual doses of 600 mg twice weekly, but the incidence increases with twice-weekly doses >900 mg. The incidence also increases if the dosing interval is increased to ≥1 week.[127],[128] Unless the symptoms are severe, discontinuation of the drug is unnecessary. Because C.M. is receiving rifampin 900 mg twice weekly, her dose should be reduced to 600 mg and administered daily until the symptoms subside. Temporary administration of a nonsteroidal anti-inflammatory drug has been used to alleviate the flulike symptoms. Twice-weekly therapy may then be resumed as long as the dose of rifampin does not exceed 600 mg.

Case 68-3, Question 2: One month after beginning her twice-weekly DOT regimen, C.M. exhibited symptoms of myalgias, malaise, and anorexia. Laboratory data were normal except for a slightly decreased platelet count. Could C.M.'s symptoms be related to her drug therapy? What adverse reactions other than hepatotoxicity should be anticipated in a patient receiving rifampin?

HEPATOTOXICITY

Rifampin (rifapentine) is associated with a <1% rate of hepatotoxicity. Therefore, the risk of drug-induced hepatotoxicity is greater with isoniazid than that with rifampin. On occasion, rifampin can cause hepatocellular injury and potentiate hepatotoxicity of other antituberculosis drugs.[116] Although elevations of liver enzymes may be seen, rifampin is more likely to produce cholestasis, as manifested by increases in alkaline phosphatase and hyperbilirubinemia without hepatocellular injury.[116] Elevations of all LFTs may be seen transiently during the first month of rifampin therapy, but they are usually benign.[34]

THROMBOCYTOPENIA

Thrombocytopenia is more frequently associated with intermittent or interrupted rifampin administration, likely caused by production of immunoglobulin G and immunoglobulin M antibodies to rifampin. These antibodies likely fix complement onto platelets, resulting in platelet destruction. Hypothetically, intermittent or interrupted rifampin therapy results in increased antibody production. Once thrombocytopenia occurs with rifampin, its subsequent use is contraindicated because the problem will likely recur.[129],[130]

MISCELLANEOUS REACTIONS

In addition to the side effects associated with high-dose, intermittent therapy, 3% to 4% of patients taking normal doses of rifampin may experience adverse reactions.[129] The most common of these are nausea, vomiting, fever, and rash. Other reactions to rifampin include the hepatorenal syndrome, hemolysis, leukopenia, anemia, and arthralgias as part of a suspected drug-induced lupus syndrome.[34],[131] Development of these latter reactions requires discontinuation of the drug.

ACUTE RENAL FAILURE

Acute renal failure has been reported rarely with rifampin. This hypersensitivity reaction may occur with both intermittent and daily

administration and may last as long as 12 months.[127] Rifampin should be discontinued, and other drugs (eg, pyrazinamide and ethambutol) should be given. Doses of ethambutol and pyrazinamide should be adjusted for renal dysfunction, if necessary. Both rifampin and isoniazid may, however, be given in normal dosages to patients with preexisting renal failure.[132],[133]

DISCOLORATION OF BODY FLUIDS

Another important characteristic of rifampin relates to its chemical makeup. It is an orange-red crystalline powder that is widely distributed in body fluids. As a result, it can discolor saliva, tears, urine, sweat, and cerebrospinal fluid (CSF).[34] Patients using rifampin should be warned of this effect and cautioned not to use soft contact lenses because of possible discoloration. This effect may also be used to monitor adherence to rifampin therapy.

DRUG INTERACTIONS

Rifampin is a very potent inducer of CYP3A4 and also induces other CYP isoenzymes, including CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, and CYP3A5.[34],[134],[135] Rifampin induces phase 2 drug-metabolizing enzymes (eg, uridine 5'-diphospho-glucuronosyltransferase, sulfotransferases) and expression of transporter proteins (eg, P-glycoprotein, multiple-drug resistance protein 2, organic anion-transporting polypeptide).[134] Complete induction of these isoenzymes and transport proteins occurs ~1 week after starting rifampin and returns to baseline ~2 weeks after discontinuing the drug.[134] Rifamycins differ in their ability to induce CYP isoenzymes, in which rifampin is the most potent, rifapentine is intermediate, and rifabutin is the least potent enzyme inducer.[34] Rifampin increases the metabolism of protease inhibitors, integrase strand inhibitors, certain non-nucleoside reverse transcriptase inhibitors (NNRTIs), macrolide antibiotics, azole antifungal agents, corticosteroids, oral contraceptives, methadone, warfarin, cyclosporine, tacrolimus, theophylline, phenytoin, quinidine, diazepam, propranolol, metoprolol, sulfonylureas, verapamil,

nifedipine, diltiazem, enalapril, and simvastatin.[34,126] Although the patient is receiving rifampin, it may be necessary to monitor serum concentrations of the aforementioned drugs, when appropriate, or increase their dosages. Also, females who are taking rifampin and oral contraceptives should use an alternative method of birth control. When treating any patient with rifampin, the health care professional should carefully evaluate all concomitant medications for the possibility of drug–drug interactions.

Isoniazid–Rifampin

HEPATOTOXICITY

Case 68-3, Question 3: Will the combination of isoniazid and rifampin increase the risk of hepatotoxicity in C.M. to a greater extent than does either drug alone?

Some initial evidence suggested that the concomitant use of isoniazid and rifampin was associated with a greater incidence of hepatotoxicity. The mechanism was thought to be attributable to rifampin induction of the metabolism of isoniazid to either monoacetylhydrazine or to other hepatotoxic products of hydrolysis. Steele et al[122] performed a meta-analysis reviewing the incidence of hepatitis using regimens that contained isoniazid without rifampin, rifampin without isoniazid, and regimens containing both drugs. They found the incidence of clinical hepatitis was greater in regimens containing both isoniazid and rifampin (2.7%) versus regimens of isoniazid alone (1.6%), but this effect was additive, not synergistic, and therefore expected.[122] The use of the two drugs together, therefore, is not contraindicated, but caution should be used in high-risk groups such as the elderly, alcoholics, those receiving concomitant hepatotoxic agents, and those with preexisting liver disease.[116]

Ethambutol

OPTIC NEURITIS

CASE 68-4

QUESTION 1: S.E., a 65-year-old female, was placed on daily rifampin 600 mg, isoniazid 300 mg, pyrazinamide 1500 mg, and ethambutol 1200 mg for initial treatment of active pulmonary TB. Two months after the initiation of therapy, she began to report blurred vision. A routine eye examination and visual field tests yielded a diagnosis of optic neuritis. No evidence was seen of glaucoma, cataracts, or retinal damage. Laboratory tests were within normal limits except for an elevated serum uric acid (9.7 mg/dL) and a slightly elevated serum creatinine (1.6 mg/dL). No symptoms of joint pain were associated with the elevated serum uric acid, and there was no history of gout. Her estimated creatinine clearance based on her weight of 143.30 pounds (65 kg) was 36 mL/minute.

Could the visual problem and increased uric acid levels be related to her medications?

S.E.'s decrease in visual acuity is compatible with ethambutol-induced optic neuritis. This condition is characterized by central scotomas, loss of red-green color vision, or, less commonly, a peripheral vision defect. The intensity of these ocular effects is related to the duration of continued therapy after decreased visual acuity is first noted. Optic neuritis is related to both dose and duration, and it rarely occurs at doses of 15 mg/kg.[136–138] The incidence is estimated to be 6% for doses of 25 mg/kg and increases to 15% for doses in excess of 35 mg/kg. Recovery, which may take months, is usually, but not always, complete when the drug is discontinued.

The optic neuritis manifested in S.E. is probably caused by the use of an increased ethambutol dose (18.5 mg/kg) in a patient with impaired renal function. Because ethambutol adds no additional benefit to isoniazid and rifampin after the first 2 months for susceptible organisms, it can be discontinued. Ethambutol is excreted by the kidney (50%–80%), and her ethambutol dosing interval should have been increased based on the decline in creatinine clearance.[132] Her visual acuity should be monitored closely through periodic eye examinations, and she should be

instructed to contact her physician immediately if she experiences any further visual changes.

S.E.'s elevated serum uric acid also may be attributed to her ethambutol and a decline in her renal function, but it is more likely caused by pyrazinamide, which decreases the tubular secretion of urate.[101] Asymptomatic hyperuricemia secondary to drugs usually does not require treatment.

SPECIAL TREATMENT CONSIDERATIONS

Elderly Patients

INCIDENCE

CASE 68-5

QUESTION 1: G.H., a 75-year-old, 176.37-pound (80-kg) male who resides in a nursing home, becomes disoriented, refuses to eat, and has a productive cough. Physical examination reveals a thin male with slight difficulty breathing. Laboratory findings are essentially normal, with the exception of a slightly elevated blood urea nitrogen of 25 mg/dL and serum creatinine of 1.3 mg/dL. Chest radiography reveals infiltrates in the right lower lobe. He has a history of congestive heart failure, which is well controlled. Blood, urine, and sputum samples are sent for culture and susceptibility testing. The initial Gram stain finding is negative. Because the nursing home has recently had two cases of active TB, a PPD skin test and sputum smear for AFB are ordered. The PPD skin test induration is 16 mm, and the sputum smear result is positive for AFB. G.H.'s admission skin test result several months ago was negative.

What is the typical presentation of TB in the elderly? What is the appropriate treatment of active disease in G.H.? Is the incidence of drug side effects higher in the elderly? Should other patients in close contact with G.H. receive isoniazid therapy?

In 2019, the overall case rate of TB in adults ages 65 years or older was higher than all other age groups (4.5/100,000 population).[11] Similar to other age groups, the case rate for persons ages 65 years or older has declined every year since 1993 when the

case rate was 17.7/100,000 population.[11] In 2019, 1.8% of TB cases were reported in residents of long-term care facilities,[11] and the case rate for nursing home residents was 1.8 times higher than that for elderly persons living in the community.[139] Active TB disease in the elderly has been attributed to decreased immune function followed by reactivation of an earlier infection, but active disease is a common, endemic infection in nursing home patients with no previous immunity (negative skin test) to *M. tuberculosis.*[139],[140] The incidence of positive TST results increases after patients have been in the nursing home >1 month. Therefore, all patients entering a nursing home should be tested with 5 TU of PPD. If the initial test result is negative and a source case is present in the nursing home (as illustrated by this case), this test should be repeated in 1 month. The rate of TST conversion (from negative to positive test results) in this population is ~5%. If these recent converters are not treated with isoniazid, ~17% will develop progressive pulmonary TB.[141]

DIAGNOSIS

Diagnosis of active TB in elderly patients is difficult because classic symptoms of cough, fever, night sweats, and weight loss are often absent, and elderly patients may describe their symptoms poorly. The chest radiograph and PPD skin test results may be the only signs of TB infection.[139],[141] Frequently, the chest radiograph finding is atypical, resembling pneumonia or worsening heart failure. Chest radiographs in the elderly are less likely to reveal upper lobe infiltration; however, more commonly they will show extensive infiltration of both lungs.[142] If the patient's clinical disease is caused by reactivation, the chest radiograph often shows apical infiltrates or nodules. If the disease is progressing from an initial infection, as in the case of G.H., lower lobe infiltrates may be present.[139] TB in this population may present clinically with changes in activities of daily living, chronic fatigue, cognitive impairment, anorexia, or unexplained low-grade fever. Nonspecific signs and symptoms that range in severity from subacute to chronic and that persist for weeks to months must alert clinicians to the possibility that unrecognized

TB is present.[143] Sputum examination for *M. tuberculosis,* and AFB smear and culture should be performed in all patients, including the elderly.

TREATMENT OF ACTIVE DISEASE IN THE ELDERLY

The principles of TB treatment are the same for the elderly as that for any other age group.[34],[139] Because G.H. has clinical symptoms of a respiratory infection, positive sputum smear results for AFB, and a positive TST result, he should be treated with a four-drug regimen for active TB disease. Most TB cases in elderly patients are caused by drug-susceptible strains of *M. tuberculosis;* however, notable exceptions would be older patients who are from a country or region where the prevalence of drug-resistant strains is high, persons who have been inadequately treated in the past, or persons who acquired the infection from a recent contact known to be infected with drug-resistant *M. tuberculosis.*[143] G.H.'s drug regimen should include rifampin 600 mg, isoniazid 300 mg, pyrazinamide 2000 mg, and ethambutol 1600 mg daily for 8 weeks followed by rifampin and isoniazid daily or thrice weekly for 16 weeks (DOT). Another option might be isoniazid, rifampin, pyrazinamide, and ethambutol daily for 2 weeks, followed by twice weekly for 6 weeks, then isoniazid and rifampin twice weekly for 16 weeks.[143] Some clinicians prefer treating the elderly with 9-month regimens of rifampin and isoniazid. G.H. should also receive pyridoxine 10 to 50 mg daily.[68]

ADVERSE DRUG EFFECTS

Although isoniazid-induced hepatitis is more common in elderly patients, both rifampin and isoniazid are generally well tolerated within this age group, with major hematologic or hepatic side effects occurring in 3% to 4% of patients.[144] Therefore, serum aminotransferases should be assessed at baseline, and G.H. should be observed monthly for clinical signs of hepatitis. As discussed earlier, routine monitoring of LFTs remains controversial because transient, asymptomatic elevations do occur among the elderly.[144]

Although uncommon at 600 mg, rifampin given twice weekly may cause a greater incidence of flulike symptoms. Because potential drug interactions with isoniazid and rifampin are possible, any medication added to the patient's regimen should be carefully evaluated. Considering that G.H. has age-related decreased renal function, signs of ethambutol-induced visual dysfunction should be monitoring carefully.

TREATMENT OF LATENT INFECTION IN THE ELDERLY

Treatment of elderly patients with positive TST or IGRA results but no active TB disease with isoniazid 300 mg daily for 6 to 9 months is essential if a source case is present in the nursing home. Stead et al[141] reported only 1 case of active disease in patients receiving therapy for latent TB infection compared with 69 cases in untreated patients. In patients with recently converted skin tests, one patient in the group receiving isoniazid therapy had active disease compared with 45 who received no treatment.[141] Daily rifampin for 4 months or weekly isoniazid plus rifapentine for 12 weeks are also acceptable regimens in the elderly.[115],[139]

Multidrug-Resistant Organisms

DEFINITION AND ETIOLOGY

CASE 68-6

QUESTION 1: M.S., an ill-appearing 29-year-old Asian male, is admitted to the hospital with signs and symptoms of pneumonia. He is coughing, and his chest radiograph indicates bilateral infiltrates. He is placed in respiratory isolation pending the results of sputum testing for *M. tuberculosis.* He states that he was diagnosed with TB ~3 months ago, and treatment was initiated with the RIPE regimen. However, he stopped taking his medication after 1 month. An HIV test was performed 3 months ago, the result of which was negative.

What is the likelihood of acquired drug resistance in *M. tuberculosis*?

In the United States, isoniazid resistance was 14.1% and resistance to both isoniazid and rifampin was 5.4% in patients with

previous TB in 2019.[11] Resistance in *M. tuberculosis* is either primary or acquired. Primary drug resistance occurs when a patient harbors a resistant strain before any drugs have been administered. Acquired drug resistance occurs when resistant subpopulations are selected as a result of treatment errors, such as addition of a single drug to a failing regimen, inadequate primary regimen, failure to recognize resistance, and, most importantly, nonadherence to the prescribed regimen. Sporadic ingestion, inadequate dosages, or malabsorption of medications can cause susceptible *M. tuberculosis* strains to become resistant to multiple drugs within a few months.[145],[146] These resistant organisms can then be transmitted to persons who have never received treatment and lead to primary resistance in those patients.

M.S. is a foreign-born person of Asian ethnicity and may have primary resistance from his country of origin, making a detailed exposure history essential for the treatment of his infection. M.S. is also an example of the problem of treatment failure caused by nonadherence and the potential development of drug-resistant organisms. Homelessness and lack of awareness of the severity of TB have been shown to be significantly associated with interruptions in TB therapy.[147] Therefore, educational efforts to improve a patient's understanding of TB disease are critical for appropriate treatment of the disease.

Many factors can affect the outcome of therapy for MDR-TB, including HIV status, treatment adherence, the number of drugs to which the tubercle bacilli remain susceptible, and the time since the first diagnosis of TB.[148–150] In one study, 77% of patients with MDR-TB had sputum cultures convert to a negative finding in a median time of 60 days (range, 4–462 days), but 23% of patients never converted to negative culture results.[150] Of the patients who converted, 60% converted after 4 months of therapy.[150] Predictors of a longer time for sputum culture conversion were high initial sputum colony counts, bilateral cavitation on chest radiograph, previous treatment of MDR-TB, and the number of drugs the initial isolate was resistant to at the beginning of therapy.[150]

Case 68-6, Question 2: Can M.S. be cured by drug therapy, and, if so, how should he be treated?

According to the World Health Organization, overall treatment success for MDR-TB is 57%, which is lower than is the treatment success for drug-susceptible TB (85%).[9] Because his recent HIV test result was negative, M.S. may have a higher probability of treatment success. In HIV-negative patients, 32 (97%) of 33 patients with MDR-TB were cured, and these patients received an average of five second-line drugs.[149] Only one relapse occurred 5 years after treatment.[149] Therefore, M.S.'s current regimen should be reevaluated, drug susceptibility testing determined, and the patient referred to a specialist or consultation at a specialized treatment center.[35] Molecular drug resistance testing should be performed to evaluate resistance to rifampin, which is a reliable surrogate for MDR-TB. If rifampin resistance is detected, the patient should begin therapy for MDR-TB, and susceptibility testing should be performed for all first-line agents, fluoroquinolones, and aminoglycosides, although results may not be available for several weeks.[35] Globally, fluoroquinolone resistance was 20.1% in MDR-TB isolates, so resistance to fluoroquinolones must be excluded.[9]

Treatment guidelines for MDR-TB recommend initiating therapy with at least five drugs with documented susceptibility or with high likelihood of susceptibility against the patient's isolate.[35] It is preferable to avoid drugs that were previously used for treatment. Bedaquiline and either levofloxacin or moxifloxacin should be included in the initial treatment regimen. Additional drugs for treatment of MDR-TB include linezolid, clofazimine, cycloserine, amikacin, ethambutol, and pyrazinamide. The intensive phase should be continued for 5 to 7 months after culture conversion. The continuation phase should include four drugs with a total treatment duration of 15 to 21 months.[35] Treatment should be given by DOT, but only 40% of patients with MDR-TB complete a full 18 to 24 months of therapy.[151]

The efficacy of a standardized treatment regimen for a shorter duration of therapy has been evaluated in patients with documented MDR-TB.[152],[153] A recent study compared a short-course regimen for 9 to 11 months to an individualized regimen for 18 to 24 months for treatment of MDR-TB.[153] The study population consisted of 424 patients, of which 32.6% were infected with HIV with a median $CD4^+$ count of 248 cells/μL and 77.2% had cavitary lesions. The short-course regimen consisted of high-dose moxifloxacin, clofazimine, ethambutol, and pyrazinamide for a total of 40 weeks, and kanamycin, isoniazid, and prothionamide were also administered for the first 16 weeks.[153] The intensive phase could be extended to 20 or 24 weeks if AFB smear results were still positive at 16 or 20 weeks, respectively. Daily moxifloxacin doses were 400, 600, and 800 mg for body weights <33 kg, 33 to 50 kg, and >50 kg, respectively. The longer course regimen was the standard regimen of the World Health Organization for the treatment of MDR-TB. The primary outcome (favorable status) was reported in 78.8% in the short-course group and 79.8% in the longer course regimen, which demonstrated noninferiority.[153] Unfavorable bacteriologic outcomes were more common in the short-course group (10.6% vs 5.6%), and death was more common in the short-course group (8.5% vs 6.4%).[153] Median time to negative AFB and culture results did not differ significantly between groups. These results suggest that it may be possible to adequately treat patients with MDR-TB with shorter courses of therapy. However, prothionamide and kanamycin are unavailable, and clofazimine is difficult to procure in the United States.

Fluoroquinolones are active against mycobacteria, including *M. tuberculosis,* and they penetrate rapidly into macrophages and exhibit intracellular mycobactericidal activity.[148] Fluoroquinolones inhibit DNA gyrase in *M. tuberculosis,* but the other molecular target of these agents, topoisomerase IV, is absent.[148] Ciprofloxacin, ofloxacin, and levofloxacin have been used long term for the treatment of mycobacterial infections and were well tolerated with few serious adverse effects.[154],[155] Limited data suggest that moxifloxacin is an acceptable option in the treatment of MDR-TB.[156]

Selection of fluoroquinolone resistance has been observed in vivo, and complete cross-resistance within the class is the accepted rule.[148]

Bedaquiline was FDA approved in late 2012 as part of combination therapy with at least three or four other drugs in adults with pulmonary MDR-TB when other alternatives are not available. Bedaquiline is a novel drug that inhibits mycobacterial adenosine 5′-triphosphate synthase, thereby inhibiting energy production in *M. tuberculosis*.[157] The drug is available as 100-mg tablets, and the recommended dosage is 400 mg daily for 2 weeks followed by 200 mg thrice weekly for 22 weeks.[157] Bioavailability of bedaquiline is increased twofold when administered with food, and each dose should be administered by DOT.[157] Bedaquiline is metabolized by CYP3A4, and it is recommended to avoid concomitant administration of bedaquiline with moderate (eg, efavirenz) and strong (eg, rifamycins) CYP3A4 inducers. Strong CYP3A4 inhibitors may increase systemic exposure and adverse events of bedaquiline, and use of strong CYP3A4 inhibitors for >14 consecutive days should be avoided while the patient is receiving bedaquiline.[157] Bedaquiline can cause QT prolongation, and additive prolongation may occur with other drugs known to prolong the QT interval, such as fluoroquinolones.

Bedaquiline received accelerated FDA approval based on the surrogate marker of time to sputum culture conversion in phase 2 studies. In the first study, 47 patients with MDR-TB received bedaquiline or placebo added to a preferred background regimen of kanamycin, ofloxacin, ethionamide, pyrazinamide, and cycloserine or terizidone for 8 weeks.[158] After 8 weeks, the background regimen was continued for a total of 96 weeks. Time to sputum culture conversion was significantly reduced in the bedaquiline group, and sputum culture results were negative in 48% of patients in the bedaquiline group compared to 9% in the placebo group at 8 weeks.[158] After 24 weeks, 81% of patients in the bedaquiline group had negative sputum culture results compared to 65.2% in the placebo group.[159] However, after 104 weeks, treatment success was

achieved in 52.4% and 47.8% of patients in the bedaquiline and placebo groups, respectively.[159]

In the second study, 160 patients with pulmonary MDR-TB received either placebo or bedaquiline 400 mg daily for 2 weeks followed by 200 mg thrice weekly for 22 weeks with the same background regimen described previously.[160] After 24 weeks, patients continued the background regimen for a total of 18 to 24 months. The median time to sputum culture conversion was 83 days in the bedaquiline group compared to 125 days in the placebo group ($P > .001$).[160] Compared to placebo, significantly more patients in the bedaquiline group had negative culture results at 24 weeks (79% vs 62%, $P = .008$) and at 120 weeks (62% vs 44%, $P = .04$).[160] However, mortality was significantly higher in patients receiving bedaquiline (13% vs 2%, $P = .02$).[160]

Pretomanid is an oral nitroimidazole that was approved by the FDA in 2019 as part of a combination regimen with bedaquiline and linezolid for the treatment of adults with pulmonary XDR-TB and treatment-intolerant or nonresponsive MDR-TB.[161] It blocks cell wall production by inhibiting mycolic acid biosynthesis. The dose is 200 mg daily for 26 weeks, and the drug should be taken with food. Compared with the fasting state, maximum serum concentrations and area under the serum concentration–time curve were increased by 76% and 88%, respectively, when administered with a high-fat, high-calorie meal. Pretomanid is metabolized via multiple pathways, and CYP3A4 is responsible for 20% of metabolism. Only 1% of pretomanid is excreted in the urine as unchanged drug.

Human Immunodeficiency Virus Infection

TREATMENT OF ACTIVE DISEASE

CASE 68-7

Question 1: F.R. is a 32-year-old male who presents to the emergency department with mild pleuritic chest pain and a productive cough. He also has experienced weight loss, fatigue, and night sweats for the past 3 weeks. On

questioning, F.R. states that he is bisexual and frequently engages in unprotected sex. Chest radiography finding reveals bilateral interstitial infiltrates. Sputum samples are ordered, and the workup includes AFB smear and culture. A PPD skin test is placed, and an HIV test is ordered. The results of the AFB smear and HIV test are positive, and the induration from the PPD is 6 mm. A $CD4^+$ count is ordered, which is 150 cells/μL.

What are the clinical manifestations of active TB in patients infected with HIV? How effective is skin testing in the diagnosis of TB infection in patients infected with HIV? What diagnostic tests should be performed in F.R.?

HIV infection is an important risk factor for active TB disease because HIV infects and destroys $CD4^+$ cells, leading to impaired cell-mediated immunity. The immunodeficiency allows for rapid development of active TB disease in a person who is infected with *M. tuberculosis.* TB is a common opportunistic infection in persons infected with HIV, but unlike other opportunistic infections in this population, $CD4^+$ cell count is not a reliable predictor for risk for TB disease.[67] Active TB disease can occur at any $CD4^+$ cell count, but the risk increases as a patient's immunodeficiency progresses.

Common symptoms of active disease (productive cough, fever, sweats, weight loss, fatigue) may be present in HIV-infected individuals, but the clinical manifestations of TB depend on the severity of the immunodeficiency at the time of presentation. TB in an HIV-infected person will clinically resemble TB in an HIV-uninfected person if the immunodeficiency is less severe ($CD4^+$ count >200 cells/μL).[162] The disease will primarily be limited to the lungs in these patients, and upper lobe involvement with or without cavitation will be seen on chest radiography findings. However, the findings on chest radiography are markedly different in patients with advanced HIV disease ($CD4^+$ count <200 cells/μL). Lower lobe, middle lobe, interstitial, and miliary infiltrates are common, whereas cavitation is seen infrequently.[67],[162] In these patients, TB may be difficult to distinguish from other HIV-related pulmonary opportunistic infections (*Pneumocystis jirovecii, M. avium* complex), and TB should be ruled out in any HIV-infected patient with pulmonary symptoms. Patients with advanced HIV disease may also have normal chest radiograph findings but still have positive sputum

smear results for AFB and positive cultures for *M. tuberculosis*.[162] Therefore, a normal chest radiograph finding does not exclude the possibility of active TB disease. Extrapulmonary TB is more common in HIV-infected persons with $CD4^+$ counts <200 cells/μL.[67],[162] Because of F.R.'s clinical presentation and positive HIV test result, a high index of suspicion and diagnostic workup for active TB are appropriate.

A PPD skin test may be placed on HIV-infected patients with suspected TB infection, but sensitivity and specificity of skin testing are poor in patients with HIV infection. Only about 30% to 50% of patients with AIDS and TB will respond to a PPD skin test with an induration >10 mm. Therefore, an induration of ≥5 mm is considered to be a positive reaction in this population.[50] F.R.'s reaction of 6 mm to the TST should be considered positive. Theoretically, the sensitivity and specificity of IGRAs are also limited in patients with HIV infection because the tests depend on adequately functioning $CD4^+$ cells. In a study of 294 HIV-infected subjects, indeterminate results were more likely to occur in subjects with a $CD4^+$ count <100 cells/μL compared with those with a $CD4^+$ count of ≥100 cells/μL.[163] Additional studies found only 64% sensitivity for detection of active TB disease, and false-negative results occurred in ~25% of HIV-infected patients with documented pulmonary TB.[164],[165] These studies suggest that IGRAs should not be used alone to exclude active TB in this population.

The diagnostic workup for HIV-infected persons is similar to that for HIV-uninfected persons. Chest radiography and sputum samples for AFB smear and culture of three sputum specimens should be obtained.[162],[166] AFB smear results may be negative in patients with pulmonary TB who have advanced immunodeficiency and noncavitary disease.[162] NAA tests can be used to assist in evaluation of HIV-infected persons with positive AFB smear results, and a positive NAA test result in a patient whose AFB smear result is positive likely represents active TB.[67],[162] Drug susceptibility testing for all first-line agents should be performed on the initial isolate for all patients, and testing should be repeated if sputum culture results remain positive after 4 months of treatment or become positive after

at least 1 month of negative culture results.[162] Susceptibility testing of second-line agents should be limited to specimens from patients who have received prior therapy, are contacts of persons with drug-resistant TB disease, have demonstrated resistance to rifampin or other first-line agents, have positive culture results after 3 months of therapy, or are from regions with a high prevalence of MDR-TB or XDR-TB.[167] Molecular drug resistance tests may also be used to yield faster results. Patients with symptoms of extrapulmonary TB should undergo needle aspiration or tissue biopsy of skin lesions, lymph nodes, or pericardial or pleural fluid, and blood cultures for AFB should be obtained.[67]

Case 68-7, Question 2: What is the preferred treatment regimen for TB in F.R.?

Given his symptoms and positive AFB smear result, F.R. should be started on multiple-drug therapy for treatment of active TB disease. DOT is recommended for all patients with HIV-related TB.[34],[67],[162] F.R.'s treatment plan should be based on completion of the total number of doses ingested rather than on the duration of therapy. Principles and recommendations for treatment of TB in HIV-infected adults are similar to those for HIV-uninfected adults, with a notable exception (Table 68-2). The initial 8-week treatment phase in F.R. should include rifampin or rifabutin, isoniazid, pyrazinamide, and ethambutol administered daily by DOT (7 days/week for 56 doses or 5 days/week for 40 doses).[34],[162] Ethambutol may be discontinued when rifampin and isoniazid susceptibility are confirmed. However, twice- or thrice-weekly dosing regimens during the intensive or continuation phase have been associated with increased risk of treatment failure or relapse with acquired rifamycin resistance; therefore, intermittent dosing regimens are not recommended.[162] F.R. should also receive supplemental pyridoxine. After the initial phase, if no drug resistance is evident on susceptibility or molecular testing, F.R. can be treated with rifampin (or rifabutin) and isoniazid daily by DOT for a minimum of 18 weeks.[162]

Case 68-7, Question 3: How should TB therapy be monitored in F.R.?

If F.R. had cavitary disease on chest radiography finding or if culture results are positive after 2 months of intensive therapy, treatment with rifampin or rifabutin and isoniazid should be continued to complete a total of 9 months (39 weeks) of therapy. If F.R. was suspected of having extrapulmonary disease caused by drug-susceptible strains, the recommended treatment is rifampin or rifabutin, isoniazid, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for 4 to 7 months. However, longer durations of therapy are recommended for extrapulmonary TB involving the CNS (meningitis or tuberculoma) or bone and joints. For these infections, many experts recommend 9 to 12 months of therapy.[162]

Baseline and monthly evaluations of hepatic function, renal function, complete blood count, and $CD4^+$ cell count are recommended in all HIV-infected patients with active TB disease.[67] In the absence of symptoms, elevations of alanine transaminase (ALT) more than three times the upper limit of normal should not cause a change in therapy.[162] If the ALT is more than three times the upper limit of normal in a patient with symptoms, more than five times the upper limit of normal regardless of symptoms, or if a significant increase in alkaline phosphatase and/or bilirubin occurs, hepatotoxic drugs should be stopped and the patient evaluated.[162] At least three anti-TB drugs should be initiated (eg, ethambutol, fluoroquinolone, aminoglycoside) as a bridging regimen until the etiology of hepatotoxicity can be determined and a long-term regimen designed. After the patient's ALT decreases to two and a half times the upper limit of normal, the first-line hepatotoxic agents may be restarted by adding back each individual drug to the bridging regimen at 7-day intervals, and ALT should be monitored frequently.[162] For pulmonary TB, at least one sputum specimen should be obtained monthly for AFB smear and culture until two consecutive specimen results are culture negative.[67],[162] If the AFB smear result is positive at the initiation of treatment, AFB smears

may be obtained every 2 weeks to provide an early assessment of bacteriologic response to therapy.[34],[67] Results of sputum samples obtained after the initial 8-week treatment phase are important because determination of the duration of the continuation phase will be based on these results. Susceptibility testing should be performed on all isolates, and susceptibility testing should be repeated on a newly obtained sputum sample if cultures are positive for *M. tuberculosis* after 3 months of therapy.[67] Patients with positive culture results at or after 4 months of therapy should be considered treatment failures.

At every visit, patients should be questioned about adherence to therapy and possible adverse events to the treatment regimen. If a patient is experiencing adverse events, the first-line drugs should not be discontinued permanently without strong evidence that a specific agent is the cause of the adverse event.[67],[162] Drug concentration monitoring may be useful to help guide therapy in patients who respond slowly to the prescribed treatment regimen.[168]

CASE 68-7, QUESTION 4: When should antiretroviral therapy (ART) be initiated in F.R.?

Optimal management of active TB disease in patients infected with HIV requires treatment of both infections. TB in HIV-infected patients with advanced immunodeficiency can be rapidly progressing and fatal; therefore, sequential treatment of TB followed by treatment of HIV is not recommended.[162] In patients with HIV infection, $CD4^+$ cells multiply in response to *M. tuberculosis,* and then HIV replication accelerates within the lymphocytes and macrophages, which leads to progression of HIV disease. Therefore, initiation of ART can prevent progression of HIV disease and reduce morbidity and mortality associated with TB and other opportunistic infections.[67],[162] However, this approach may be associated with cumulative drug toxicities, significant drug interactions, higher pill burden, and the potential for development of immune reconstitution inflammatory syndrome (IRIS).[67],[162]

Three studies addressed the optimal timing to initiate ART during treatment of active TB disease.[169–171] In ART-naive patients, ART should be initiated within 2 weeks of starting TB therapy in patients with a $CD4^+$ count <50 cells/μL.[162] Early initiation of ART significantly reduces mortality in these patients, but the risk of IRIS is increased. In patients with $CD4^+$ counts of ≥50 cells/μL who present with severe TB disease (low Karnofsky score, low body mass index, low hemoglobin, low albumin, organ system dysfunction, or extensive disease), studies suggest that ART should be initiated within 2 to 4 weeks of starting TB therapy. In patients with $CD4^+$ counts of ≥50 cells/μL who do not have severe TB disease, ART should be initiated within 8 to 12 weeks of initiating TB therapy.[169–171] Guidelines recommend initiation of ART within 8 weeks of starting TB treatment in patients with $CD4^+$ counts of ≥50 cells/μL.[162] If IRIS develops, neither therapy for TB nor HIV should be discontinued. Because F.R. is ART naive and his $CD4^+$ count is 150 cells/μL, ART should be initiated within 8 weeks of starting treatment for active TB.

If F.R. was receiving ART when diagnosed with TB, treatment for TB should be started immediately, and ART should be modified to maintain virologic suppression while reducing the risk for drug–drug interactions.[162] ART should not be withheld simply because the patient is being treated for TB, and a rifamycin should not be excluded from the treatment regimen for fear of interactions with certain antiretroviral agents.[34,162] Exclusion of a rifamycin will likely delay sputum conversion, prolong the duration of therapy, and possibly result in a poor outcome.

Case 68-7, Question 5: Because F.R.'s $CD4^+$ count is 150 cells/μL, the decision is made to begin ART after the initial 8-week intensive phase to decrease the potential for IRIS. What is IRIS? What drug interactions are likely in an HIV-infected patient receiving treatment for TB and HIV?

IRIS occurs in ~30% of patients who begin therapy for both HIV and TB in close temporal proximity.[162,172] This syndrome is thought to reflect recovery of immune responses to *M. tuberculosis* and usually occurs in the first 1 to 4 weeks after initiation of ART.[162] IRIS lasts for

2 to 3 months on average, but some patients may experience IRIS symptoms for months. The immune response can be an exaggerated inflammatory response during TB therapy in a patient known to have TB infection, or it may unmask a previously undiagnosed TB infection. The risk of IRIS is greater when ART is initiated within the first 2 months of TB therapy and when the $CD4^+$ count is <50 to 100 cells/μL.[67],[162] Symptoms include high fever, malaise, and local reactions in organs, depending on the location of the mycobacterial infection (eg, lungs, lymph nodes, CNS). IRIS is usually self-limiting, but supportive therapy may be required if symptoms are severe. Moderate IRIS reactions should be treated with nonsteroidal anti-inflammatory drugs without any changes to TB therapy or ART.[67] No specific treatment recommendations are available for severe IRIS; however, prednisone or methylprednisolone at doses of 1 mg/kg body weight and tapered for 1 to 2 weeks has been beneficial.[67]

Simultaneous treatment of TB and HIV can be complicated by drug interactions with the rifamycins and ART.[134],[162] Rifampin is a potent inducer of CYP isoenzymes, but rifabutin is not a potent inducer.[34],[67] Rifabutin is highly active against *M. tuberculosis,* and data from clinical trials suggest equal efficacy with rifampin- and rifabutin-based treatment regimens.[34],[162] Because of fewer drug interactions and documented efficacy, rifabutin is recommended in place of rifampin for the treatment of active TB in HIV-infected patients receiving ritonavir-boosted protease inhibitors or NNRTIs.[33],[161] However, some antiretroviral agents may either induce or inhibit CYP isoenzymes, depending on the specific drug, and may alter rifabutin serum concentrations.[34],[162]

For the NNRTIs, rifampin has been shown to decrease efavirenz exposures by 26%, but two additional studies did not show a significant effect of rifampin on efavirenz exposure.[173–175] Therefore, the preferred treatment regimens are rifampin-based TB therapy with an ART regimen consisting of efavirenz plus two nucleoside reverse transcriptase inhibitors.[162] The efavirenz dose should be 600 mg daily.[162] Efavirenz decreases rifabutin exposure by 38%, necessitating a dosage increase for rifabutin to 450 to 600 mg

daily.[162] For patients unable to take efavirenz because of early pregnancy or intolerance, nevirapine-based ART can be used, but rifampin significantly decreases nevirapine exposures.[162] If used concomitantly, the nevirapine dose should be 200 mg twice daily.[162] However, rifabutin-based TB therapy may be considered with a nevirapine-based ART regimen because dosage adjustments are not needed for either agent.[162] Concomitant administration of doravirine, etravirine, and rilpivirine with rifampin should be avoided because of significant reduction in exposures of these NNRTIs.[162]

Rifampin should not be used in patients receiving protease inhibitor– based ART, regardless of boosting with ritonavir or cobicistat, because rifampin causes a dramatic decrease in exposures of the protease inhibitors.[67],[162] Rifabutin has a negligible effect on ritonavir-boosted lopinavir or atazanavir and only moderate increases in darunavir and fosamprenavir concentrations.[162] For patients unable to tolerate efavirenz or nevirapine or if the HIV strain is resistant to NNRTIs, a rifabutin-based TB regimen is preferred with an ritonavir-boosted protease inhibitor regimen.[162] However, all protease inhibitors markedly increase rifabutin concentrations. If doses of rifabutin are not adjusted, adverse drug events, such as uveitis, neutropenia, arthralgias, and skin discoloration, may occur.[67] Therefore, the rifabutin dose should be decreased to 150 mg daily when administered with boosted protease inhibitors.[162]

HIV nucleoside and nucleotide reverse transcriptase inhibitors (tenofovir disoproxil fumarate, abacavir, emtricitabine, lamivudine) and the fusion inhibitor enfuvirtide are not metabolized by CYP isoenzymes. As a result, these agents can be administered with the rifamycins.[134],[162] Tenofovir alafenamide (TAF) is a substrate for P-glycoprotein, but intracellular concentrations of tenofovir diphosphate are higher when administered with rifampin compared to administration of tenofovir disoproxil fumarate alone. Thus, TAF may be given with rifampin-based TB regimens without dose adjustment.[162]

Rifampin decreases the concentrations of the integrase strand inhibitors. For raltegravir, the dose should be increased to 800 mg twice daily if given with rifampin, but no dosage adjustment is

recommended with rifabutin.[162] Dolutegravir may be given with rifampin, but the dose should be increased to 50 mg twice daily, which provides exposure similar to that with 50 mg daily without rifampin. Dose adjustment is not needed for dolutegravir if given with rifabutin.[176] Coadministration with elvitegravir or bictegravir with rifampin and rifabutin should be avoided.[162] Maraviroc, a CCR5 antagonist, is a substrate for CYP3A and P-glycoprotein, and concomitant administration with rifampin significantly decreases exposures.[134] The maraviroc dose should be increased to 600 mg twice daily, but no dosage adjustment is needed with rifabutin.

TREATMENT OF LATENT TUBERCULOSIS INFECTION IN HUMAN IMMUNODEFICIENCY VIRUS INFECTION

CASE 68-8

QUESTION 1: N.M. is the 32-year-old partner and roommate of F.R. Because of his close contact with F.R., he is evaluated for exposure to TB by an infectious diseases specialist. N.M.'s HIV test result is positive, and a TST produces an induration of 8 mm, which is a positive reaction. All other studies return negative findings for active TB.

Should N.M. receive treatment for latent TB infection? If so, what therapy should he receive?

The risk of N.M. developing active TB disease is significant; therefore, he should receive treatment for latent TB infection. HIV-infected persons, regardless of age, should be treated for latent TB infection.[67] In addition, HIV-infected persons who are in close contact with anyone with active TB should receive treatment for latent TB infection, regardless of TB screening test results.[162] Pape et al conducted a randomized, placebo-controlled trial of isoniazid therapy in HIV-infected patients.[177] Patients receiving placebo were six times more likely to develop active TB than were those receiving isoniazid, and patients receiving isoniazid were also less likely to develop AIDS.[177] Treatment of latent TB infection, in conjunction with ART, decreases the risk of progression from latent infection to active disease by 76%.[162] The preferred treatment for latent TB infection in

N.M. is isoniazid 300 mg daily for 9 months.[162] Isoniazid does not increase the risk of hepatitis when used with efavirenz- or nevirapine-based ART regimens.[162] N.M. should also receive pyridoxine 25 to 50 mg daily to prevent peripheral neuropathy. Rifampin for 4 months is an alternative to isoniazid, but the potential for drug interactions should be considered. Weekly isoniazid plus rifapentine is only recommended for patients receiving efavirenz- or raltegravir-based ART regimens.[162]

Pregnancy

CASE 68-9

Question 1: E.F. is a 25-year-old Hispanic female who is being treated with isoniazid 900 mg and rifampin 600 mg twice weekly for pulmonary TB. She completed 2 months of therapy with RIPE, and began the continuation regimen 2 months ago. She recently became pregnant, and her obstetrician is concerned about the possible teratogenic effects of her TB regimen.

What are the risks of TB and its treatment to the mother and the fetus? Are these drugs teratogenic?

Although concerns about the use of any medication during pregnancy always exist, it is now recognized that untreated TB represents a far greater risk to a pregnant female and her fetus than does the treatment.[34,68] TB is one of the leading nonobstetric causes of maternal mortality.[178] The World Health Organization recommends that treatment of TB in pregnant females should be the same as that for nonpregnant females, with a few exceptions.[178] Although TB drugs cross the placenta, those in the RIPE regimen are not teratogenic in humans.[179,180] In the United States, inclusion of pyrazinamide is controversial, but it has not been recommended for use during pregnancy because of insufficient safety data.[34] Pyrazinamide has been used extensively in high-burden countries and is recommended by the World Health Organization for treatment of TB in pregnancy.[34] If pyrazinamide is not included in the initial treatment regimen, the minimal duration of therapy is 9 months.[34] All

pregnant females receiving isoniazid should also receive pyridoxine 25 to 50 mg/day because of the possibility of peripheral neuropathy.

Streptomycin should not be used during pregnancy except as a last alternative because it has been associated with mild-to-severe ototoxicity in the fetus.[178] Ototoxicity can occur throughout the gestational period and is not confined to the first trimester. With the exception of streptomycin ototoxicity, the occurrence of birth defects in females being treated for TB with the abovementioned agents is no greater than that in healthy pregnant females.[181],[182] Therefore, administration of antituberculosis drugs is not an indication for termination of pregnancy.[34] Because E.F. likely became pregnant after completing the first 2 months of therapy, she should continue her current regimen for a total of 6 months because she received pyrazinamide as part of the initial regimen.

MULTIDRUG-RESISTANT TUBERCULOSIS IN PREGNANCY

Little is known about the efficacy and safety of second-line drugs for the treatment of MDR-TB during pregnancy. Two reports with small numbers of patients have suggested that treatment is effective, with no adverse effects to mother or child.[183],[184] In a study of seven females treated for MDR-TB during pregnancy, no obstetric complications or perinatal transmission of MDR-TB was observed. Five females were cured, one experienced treatment failure, and one stopped therapy prematurely.[183] No evidence of drug toxicity was seen among their children exposed to second-line drugs in utero, although one child was diagnosed with MDR-TB.[184] There are no well-controlled studies with bedaquiline in pregnancy; therefore, the drug should only be used in pregnancy if clearly needed. More data are needed, but pregnancy should not be a limitation to the treatment of MDR-TB.

LACTATION

Breast-feeding is encouraged for females who are deemed noninfectious and are receiving first-line therapy. Low concentrations of TB drugs have been measured in breast milk but have not been

reported to produce adverse effects in the nursing infant.[34] When the baby is born, E.F. may breastfeed while continuing her medication. Drug concentrations in breast milk are minimal and do not provide sufficient quantities for the treatment or prevention of TB in the nursing infant.[34],[68]

Pediatrics

CASE 68-10

QUESTION 1: A.M., a 3-year-old African American boy, is suspected of having TB. His father has been receiving treatment for TB for the past 2 months. A.M. has a productive cough, fever, and general malaise. His sputum test result is positive for AFB, and his PPD skin test result is positive (10 mm).

What is the incidence of TB in children? How should A.M. be treated?

The incidence of TB in children younger than age 5 years has declined from 1014 cases (4.0/100,000 population) in 1993 to 215 cases (2.4/100,000 population) in 2019.[11] Children commonly develop active TB disease as a complication of the initial infection with *M. tuberculosis* (primary TB), and the disease is characterized by intrathoracic lymphadenopathy, middle and lower lung lobe infiltrates, and the absence of cavitation on chest radiography.[34],[185] Because of the high risk of disseminated TB in infants and children, treatment should be started as soon as the diagnosis of TB is suspected. In general, regimens recommended for adults are also recommended for infants, children, and adolescents, with the exception that ethambutol has not been used routinely in children historically.[34] Ethambutol is often avoided because it is difficult to assess visual acuity in young children. However, the American Academy of Pediatrics does not exclude ethambutol from the initial four-drug intensive phase.[186] A.M. should be started on rifampin 15 to 20 mg/kg/day, isoniazid 10 to 15 mg/kg/day, pyrazinamide 30 to 40 mg/kg/day, and ethambutol 15 to 25 mg/kg/day (after assessment of risk versus benefit) for 2 months, followed by rifampin and isoniazid for 4 months.[34],[186] Thrice-weekly dosing is also

recommended in children.[186] If ethambutol is started and the initial isolate is drug susceptible, ethambutol should be discontinued. Many experts prefer to treat children with three drugs (rather than with four) in the initial phase because the bacillary population is usually lower than that in an adult and it may be difficult for an infant or child to ingest four drugs. Pyridoxine is recommended for infants, children, and adolescents who are receiving isoniazid.[34],[186]

A.M. should be monitored monthly for visual acuity and red-green color discrimination, and he should be examined routinely for signs and symptoms of hepatitis. Although antituberculosis medications are generally well tolerated in children, LFT results are commonly two to three times the upper limit of normal during therapy. These are often benign and transient; however, the incidence of hepatitis in children from rifampin with isoniazid may be four to six times more common than in children receiving isoniazid alone. Most hepatitis cases occur within the first 3 months of therapy and generally are associated with higher than recommended doses of isoniazid or rifampin.[122],[187]

Children and adolescents should be screened for risk factors for TB using a questionnaire, and they should be skin tested with 5 TU of PPD or an IGRA if one or more risk factors are present.[186],[188] For children younger than age 2 years, TST is preferred, and either TST or IGRA can be used in children ages 2 years and older. However, IGRA is preferred in children previously vaccinated with BCG. For latent TB infection, isoniazid plus rifapentine weekly for 12 weeks is the preferred regimen for children ages 2 years and older.[186] This regimen is not recommended in children younger than age 2 years owing to lack of pharmacokinetic data. Isoniazid for 9 months has been most commonly recommended for treatment of latent TB in this population, but adherence is poor and completion rates are low.[186] Daily rifampin for 4 months is an acceptable alternative, especially in children who cannot tolerate isoniazid or those exposed to a source case whose isolate was isoniazid resistant.[186]

Extrapulmonary Tuberculosis and Tuberculous Meningitis

CASE 68-11

Question 1: R.U. is a 64-year-old, 180.78-pound (82-kg) male who is brought to the emergency department after a 4-day period during which he became progressively disoriented, febrile to 104.90 °F (40.5 °C), and obtunded. He also had severe headaches during this time. Physical examination revealed moderate nuchal rigidity and a positive Brudzinski sign (neck resistant to flexion). An initial diagnosis of possible meningitis was made, and a lumbar puncture was ordered. The CSF appeared turbid, and laboratory analysis revealed an elevated protein concentration of 200 mg/dL, a decreased glucose concentration of 30 mg/dL, and a white blood cell count of 500/μL (85% lymphocytes). A Gram stain of the spinal fluid and a sputum smear result for AFB were negative, but the AFB smear result of the CSF was positive. Other laboratory test results were within normal limits. A diagnosis of tuberculous meningitis was made. What is the presentation and prognosis of tuberculous meningitis?

How should R.U. be treated?

Tuberculous meningitis is only one of the extrapulmonary complications of infection with *M. tuberculosis.* It is a potentially devastating disease and is associated with increased morbidity and mortality, regardless of HIV status. Successful treatment of extrapulmonary TB can usually be accomplished in 6 to 9 months with an acceptable relapse rate.[34,68,188] Some forms, such as bone or joint TB, miliary TB, or tuberculous meningitis, may require 9 to 12 months of therapy.[34] Because specimens for culture and susceptibility testing may be difficult or impossible to obtain from a site, response to treatment must be based on clinical and radiographic improvement.

Tuberculous meningitis in older persons is usually caused by hematogenous dissemination of the tubercle bacilli from a primary site, most commonly the lungs. In its early stages, tuberculous meningitis often is confused with aseptic meningitis because the Gram stain finding is negative. The most common symptoms of tuberculous meningitis are headache, fever, restlessness, irritability,

nausea, and vomiting. A positive Brudzinski sign and neck stiffness may be present. As illustrated in R.U.'s case, the CSF is usually turbid, with increased protein and decreased glucose concentrations. There is an increase in the CSF white blood cell count with a predominance of lymphocytes. Culture results of the CSF for *M. tuberculosis* may not be helpful because rates of positivity for clinically diagnosed cases range from 25% to 70%.[189] Early recognition and treatment are essential for a favorable outcome. Thus, empirical treatment before receipt of confirmatory culture and susceptibility results is common in suspected tuberculous meningitis. Multiple-drug therapy should be used because irreversible brain damage or death can occur as soon as 2 weeks after the onset of infection (not clinical symptoms).[189]

TREATMENT

Treatment should be initiated in R.U. with daily administration of rifampin 600 mg, isoniazid 300 mg, pyrazinamide 2000 mg, and ethambutol 1600 mg for the first 8 weeks.[34] After this initial phase of treatment, R.U. should receive daily rifampin and isoniazid for an additional 7 to 10 months, although the optimal duration of therapy is unknown.[34] In addition, because R.U. is older, pyridoxine 25 to 50 mg/day should be given to prevent the occurrence of peripheral neuropathy from isoniazid. It should be reiterated that rifampin can impart a red to orange color to the CSF.

Isoniazid readily penetrates into the CSF, with CSF concentrations reaching up to 100% of those in the serum. Rifampin is often included in tuberculous meningitis regimens and may be associated with reduced morbidity and mortality; however, even with inflammation, CSF concentrations of rifampin are only 6% to 30% of those found in the serum. Ethambutol should be used in the highest dosage to achieve bactericidal concentrations in the CSF because its CSF concentrations are only 10% to 54% of those in the serum. Streptomycin penetrates into the CSF poorly even with inflamed meninges.[190]

CORTICOSTEROIDS

Corticosteroids in moderate-to-severe tuberculous meningitis appear to reduce sequelae and prolong survival.[191] The mechanism for this benefit is likely owing to reduction of intracranial pressure. Dexamethasone 8 to 12 mg/day (or prednisone equivalent) for 6 to 8 weeks should be used and then tapered slowly after symptoms subside.[34],[191] Corticosteroids are likely indicated for R.U.

THERAPEUTIC DRUG MONITORING

Pharmacokinetics of the drugs used to treat tuberculosis are highly variable and depend on weight, sex, genetic traits, and underlying comorbidities. Subtherapeutic concentrations may be associated with a delayed response to therapy, increased risk of relapse, or acquired drug resistance. Several studies measured drug concentrations in patients with slow clinical response to TB treatment and found subtherapeutic concentrations for isoniazid, rifampin, ethambutol, and rifabutin in a substantial percentage of patients evaluated.[87],[192–194] In one study, time to sputum culture result conversion was longer in patients with low serum concentrations.[194] In a prospective observational study, 2-hour plasma concentrations were measured in 35 patients, and plasma concentrations were below the normal ranges in 71%, 58%, 46%, and 10% of patients for isoniazid, rifampin, ethambutol, and pyrazinamide, respectively.[195] In addition, 45% of patients had subtherapeutic concentrations for both isoniazid and rifampin. Treatment failure occurred significantly more frequently when concentrations of isoniazid and rifampin were below the normal ranges (P = .013) and below the median 2-hour drug concentration achieved in the study (P = .005).[195] In 142 patients with active TB, poor long-term outcomes were predicted by a 24-hour area under the concentration–time curve (AUC) ≤363 mg × hour/L for pyrazinamide, ≤13 mg × hour/L for rifampin, and ≤52 mg × hour/L for isoniazid.[196] Poor outcomes occurred in 32/78 patients with at least one drug with an AUC below these threshold values

compared to 3/64 patients without any low AUCs (odds ratio = 14.14; 95% confidence interval [CI] 4.08–49.1). Low rifampin and isoniazid peak concentrations and AUCs predicted acquired drug resistance in all cases.[196]

Based on these studies, therapeutic drug monitoring may be useful in patients with poor or slow clinical response to therapy and allow for dosage adjustment to achieve therapeutic drug concentrations. Additional patients who may benefit from therapeutic drug monitoring include those with severe disease, diabetes, HIV infection, renal dysfunction, and hepatic dysfunction.[197] A 2-hour postdose blood sample can be obtained to estimate the peak concentration for most drugs, whereas a 3-hour postdose blood sample would be needed for rifabutin.[197] A second blood sample at 6 hours postdose (7 hours for rifabutin) may also be obtained. Trough concentrations for most agents are below the detection limit of the assays at the end of a dosing interval and are not clinically useful.[197] Blood samples should be collected in red-top test tubes and processed immediately because some drugs are not stable at room temperature in blood or serum. Once the drug concentrations are known, comparisons can be made to the normal ranges for each drug and doses adjusted accordingly. However, normal ranges for drug concentrations have not been studied with regard to clinical outcome, and optimal drug concentrations for clinical and microbiologic efficacy are not known.[195] Although therapeutic drug monitoring may provide useful information, clinicians must remember that serum concentrations are only one factor among multiple factors affecting treatment outcomes.

Infectious Diarrhea

Rupali Jain and David T. Bearden

CORE PRINCIPLES		CHAPTER CASES
1	The most common complication of any diarrheal illness is loss of fluids and electrolytes, which in extreme cases can lead to hypovolemia, shock, and death. Depending on the degree of dehydration, fluid and electrolyte losses are replaced intravenously or orally.	**Case 69-1 (Questions 1, 2)**
2	Classification of infectious diarrheas as either an inflammatory or a noninflammatory diarrheal illness provides a basis for a focused list of suspected pathogens, thus guiding the overall diagnostic and therapeutic plan.	**Case 69-1 (Questions 3, 4)** **Case 69-4 (Question 1)** **Case 69-5 (Question 1)** **Case 69-6 (Question 1)** **Case 69-16 (Questions 1, 4)**
3	*Vibrio cholerae* 01 and 0139 are	**Case 69-2 (Questions**

	toxigenic strains of *Vibrio* species, which cause epidemic cholera; severe dehydration requiring vigorous fluid replacement may be necessary. Noncholera *Vibrio* species do not possess the virulence factors required to cause epidemic cholera. Antimicrobial treatment differs between toxigenic and nontoxigenic *Vibrio* species.	**1–3)** **Case 69-3 (Questions 1, 2)**
4	*Salmonella* species are classified as nontyphoidal and typhoidal salmonellae. Nontyphoidal salmonellae may cause the clinical syndromes of gastroenteritis, bacteremia, and localized infection, whereas typhoidal salmonellae may cause typhoid fever and chronic carriage. The role of antimicrobials in the management of salmonellosis is based on the clinical syndrome, its severity, and underlying health problems of infected persons.	**Case 69-7 (Question 1)** **Case 69-8 (Questions 1, 2)** **Case 69-9 (Question 1)** **Case 69-10 (Question 1)** **Case 69-11 (Questions 1–7)**
5	Severe dysentery caused by *Shigella* species is most commonly caused by *Shigella dysenteriae*, whereas a milder illness is typically caused by *S. sonnei*. Antimicrobials alleviate the symptoms of shigellosis and decrease the period of time that shigellae can be spread by person-to-person contact.	**Case 69-12 (Questions 1–5)** **Case 69-13 (Question 1)**
6	Fluoroquinolone resistance in *Campylobacter* species is a common finding in both developed and underdeveloped areas of the world;	**Case 69-14 (Questions 1–3)**

	when indicated, macrolide antimicrobials are recommended.	
7	Travelers to destinations where acquisition of travelers' diarrhea (TD) is a concern should bring a travel kit including medications (eg, loperamide and antimicrobials) and instructions for self-treatment at the onset of illness. The selected antimicrobial depends on the area of travel. Long-term postinfectious complications of TD may occur in some returning travelers.	**Case 69-15 (Questions 1–6)**
8	*Escherichia coli* O157:H7 is a specific toxin-producing strain of *E. coli* bacteria that can lead to the severe sequelae of hemolytic uremic syndrome.	**Case 69-16 (Questions 2, 3)**
9	*Clostridioides difficile* infection causes a wide range of severity of illness. Most cases are treated orally with vancomycin or fidaxomicin as first-line therapy.	**Case 69-17 (Questions 1-8)** **Case 69-18 (Questions 1, 2)** **Case 69-20 (Questions 1, 2)**
10	Severe *C. difficile* infection can be life-threatening and often necessitates multiple therapeutic interventions.	**Case 69-19 (Questions 1, 2)**

INTRODUCTION

Worldwide, diarrhea accounts for >2.5 million deaths annually,[1],[2] mainly affecting infants and children lacking access to clean water and improved sanitation.[3] Prolonged episodes of diarrhea lead to dehydration and malnutrition, and in children contribute to impaired

growth and developmental delay and death.[3] In the United States, about 178 million foodborne diarrheal illnesses occur each year, resulting in ~473,000 hospitalizations and 5000 deaths.[4]

Infectious diarrhea is primarily caused by the ingestion of food or water contaminated with pathogenic microorganisms (eg, bacteria, viruses, protozoa, or fungi) or their toxins (**Table 69-1**).[3] In the United States, noroviruses account for about 59% of diarrheal outbreaks, whereas common bacterial pathogens include *Campylobacter*, nontyphoidal *Salmonella*, *Shigella*, and Shiga toxin–producing *Escherichia coli*.[5]

Table 69-1
Exposures, Symptoms, and Therapy for Gastrointestinal Infections

Pathogen	Exposures	Symptoms	Diagnostic Evaluations	Drug of Choice[a,b]	Alternatives[a,b]
Salmonella (nontyphoidal)[c]	Ingestion of contaminated poultry, unpasteurized milk, juices, vegetables custards, and cream fillings; foreign travel	Nausea, vomiting, diarrhea, cramps, fever, tenesmus *Incubation*: 6–72 hours	Stool culture, NAAT	Supportive therapy only	
Salmonella (typhoidal)	Ingestion of contaminated food; uncooked eggs, foreign travel	High fever, abdominal pain, headache, dry cough, blood in stool	Stool culture, blood culture	Fluoroquinolone, third-generation cephalosporins	TMP-SMX, amoxicillin, or azithromycin
Shigella	Ingestion of contaminated salad, raw vegetables, swimming in water contaminated with sewage; foreign travel	Fever, dysentery, cramps, abdominal pain tenesmus; blood in stool *Incubation*: 24–48 hours	Stool culture or NAAT	Fluoroquinolone, azithromycin, ceftriaxone	TMP-SMX, ampicillin, if susceptible
Campylobacter	Contaminated eggs, raw milk, or poultry; foreign travel	Mild-to-severe diarrhea; blood in stool fever, systemic malaise *Incubation*: 24–72 hours	Stool culture or NAAT	Azithromycin	Ciprofloxacin
Clostridioides difficile	Antibiotics, antineoplastics	Mild-to-severe diarrhea, cramps	NAAT, GDH antigen with or without toxin detection	Oral vancomycin or fidaxomicin	Metronidazole (for mild cases)
Staphylococcal food poisoning	Custard-filled bakery products, canned food, processed meat, ice cream	Nausea, vomiting <24 hours, salivation, cramps, diarrhea; usually resolves in 8 hours *Incubation*: 2–6 hours	—	Supportive therapy only	—
Travelers' diarrhea (enterotoxigenic *Escherichia coli*, *Campylobacter*)	Contaminated food (vegetables and cheese), water; travel	Nausea, vomiting, mild-to-severe diarrhea, cramps	—	See Table 69-3	—
Shiga toxin–producing *Escherichia coli* (*E. coli* O157:H7)	Beef, raw milk, water	Diarrhea, headache, bloody stools *Incubation*: 48–96 hours	Stool cultures on MacConkey's sorbitol, molecular assays, NAAT	Supportive therapy only	—
Cryptosporidiosis	Immunosuppression, day care centers, contaminated water, animal handlers	Mild-to-severe diarrhea (chronic or self-limited); large fluid volume	Stool screening for oocytes, NAAT, EIA	See Chapter 77, Opportunistic Infections in Patients Living With HIV	—
Viral gastroenteritis (norovirus)	Community-wide outbreaks, contaminated food	Nausea, diarrhea (for 2–3 days), cramps *Incubation*: 16–48 hours	NAAT	Supportive therapy only	—

EIA, enzyme-linked immunoassay; GDH, glutamate dehydrogenase; NAAT, nucleic acid amplification test; TMP-SMX, trimethoprim–sulfamethoxazole.

[b]If susceptible. See text for details.

[c]Not all cases require antibiotic therapy. See text for details.

This chapter focuses on the diagnosis and management of the common microbial causes of acute infectious diarrhea in the United States.

DEFINITIONS

Diarrhea is often defined as three or more episodes of loose stools or any loose stool with blood during a 24-hour period, which may be accompanied by nausea, vomiting, or abdominal cramping.[5] The duration of illness is considered acute if symptoms are present for <2 weeks' duration, persistent if symptoms last for 14 to 29 days, and chronic if symptoms last ≥30 days.[5] The clinical presentation (eg, the specific symptoms, the severity, and duration of symptoms), along with the history of present illness (eg, risk factors for infection), allows for the classification of diarrheal syndromes as noninflammatory versus inflammatory illnesses. Such a classification allows the physician to consider a more focused list of potential enteropathogen(s), and based on the list of suspected organisms, a diagnostic and therapeutic plan can be developed.[1]

PATHOGENESIS

The pathogenesis of infectious diarrhea involves an interplay among bacterial virulence factors, host factors, and predisposing factors to infection. Diarrhea is more likely to occur in the setting in which an imbalance among these factors favors the enteropathogen.

Bacterial Virulence Factors

Enteropathogens possess various virulence factors that contribute to the organism's pathogenicity.[3] Enterotoxins targeting the small bowel cause net movement of fluid into the gut lumen, leading to

voluminous watery stools and potentially life-threatening dehydration. Cytotoxins targeting the colon cause direct mucosal damage, leading to fever and bloody diarrhea. Invasive properties of *Shigella* species and invasive strains of *E. coli* allow these bacteria to invade and destroy epithelial cells in the distal small bowel and colon, causing bloody or mucoid stools. Some enteropathogens induce a vigorous host response through the release of proinflammatory cytokines from intestinal epithelial cells, leading to diarrhea. Finally, enteropathogens attach and colonize the gastrointestinal (GI) mucosa, facilitating toxin delivery, invasion, dissemination, or host cell lysis.[3]

Host Defenses

The human GI tract possesses numerous defense mechanisms to protect against enteric infection. Normal bacterial flora compete for space and nutrients with potentially pathogenic organisms or produce substances, for example, short-chain fatty acids, that are inhibitory to enteropathogens.[3] Gastric acidity of the stomach prevents acid-susceptible pathogens from passing from the stomach into the intestinal tract, whereas GI mucus and mucosal tissue integrity provide physical barriers against infection. Intestinal immunity includes defensins that are bactericidal to some enteropathogens, local production of antibodies, and toll-like receptors that recognize enteropathogens and activate the immune response.[3] Intestinal peristalsis moves bacteria and their toxins along and out of the GI tract. Finally, specific host genetic factors are protective against enteric infection.[5]

Predisposing Factors

Inadequate sanitation facilities increase the risk that local inhabitants and travelers will be exposed to contaminated food and water. Outbreaks of foodborne or waterborne illnesses in both industrialized and developing countries facilitate the spread of infectious

organisms. Industrialized countries that rely on imported food items risk the possibility of importation of contaminated food products.[6] Immunocompromised hosts, such as organ transplant recipients and patients receiving immunosuppressive therapies, are more susceptible to intestinal infection. Congregate settings such as day care centers, hospitals, and extended-care facilities are high-risk settings for dissemination of disease. Other risk factors include global travel, animal exposure (in public venues), and certain sexual practices.[7]

The use of pharmacologic agents, for example, drugs that increase gastric pH, increases the risk of infection with acid-susceptible pathogens such as *Salmonella* species and *Vibrio cholerae*.[7]

MANAGEMENT OVERVIEW

Rehydration Therapy

The most acute diarrhea episodes in healthy, immunocompetent people are of limited duration and are usually self-resolving.[7] The most common complication of any diarrheal illness is loss of fluids and electrolytes, which in extreme cases can lead to hypovolemia, shock, and death.[1] Depending on the degree of dehydration, fluid and electrolyte losses are replaced intravenously or orally. Once replacement of fluid and electrolyte losses is completed, additional laboratory tests and drug therapies can be considered.

Laboratory Tests

Inflammatory diarrheal illnesses are characterized by the presence of bloody or mucoid stools. Therefore, stool specimens with red blood cells (RBCs) or occult blood, or those that contain large numbers of white blood cells, suggest infection attributable to invasive pathogens.[8]

Identification of bacterial toxins in stool specimens is a useful diagnostic tool. For example, only the toxigenic strains of *Clostridioides difficile* are pathogenic, so the presence or absence of bacterial toxins in stool specimens is more important than is a positive culture for the organism.[9]

In clinical practice, routine microbiologic identification of pathogens utilizes selective media that favor the growth of suspected pathogens.[9] Stool cultures are recommended for patients with one of the following: acute diarrhea that is severe or associated with a temperature >101.3 °F (38.5 °C); dysentery—which is an inflammatory diarrheal illness characterized by bloody or mucoid stools with abdominal cramps; profuse cholera-like watery diarrhea; dehydration; elderly or immunocompromised patients; patients in nursing homes; food handlers; and day care workers.[5] Hospitalized patients and those with recent antimicrobial exposure should be evaluated for *Clostridioides difficile* infection (CDI). Culture results of specimens from extraintestinal sites of infection (eg, blood cultures) can be used to identify the microbial etiology, especially in young children and immunocompromised hosts.

Polymerase chain reaction (PCR)-based diagnostic tests are widely available, offering improved sensitivity but focusing on genes versus virulence factors.[5]

Drug Therapy

Drug therapy for infectious diarrhea includes medications to provide symptomatic relief or to eradicate the causative pathogen.

LOPERAMIDE AND DIPHENOXYLATE/ATROPINE

Loperamide and diphenoxylate/atropine reduce the frequency of diarrheal stools by slowing intestinal transit time; in addition, loperamide possesses antisecretory properties.[10] Loperamide is preferred over diphenoxylate/atropine because of its greater efficacy, better tolerance, and over-the-counter availability. Diphenoxylate/atropine causes drowsiness, dizziness, dry mouth,

and urinary retention owing to the atropine component, and its use in the elderly is not recommended (see Chapter 107, Geriatric Drug Use).

The use of antimotility drugs is not recommended in persons with fever, bloody diarrhea,[5] or when invasive pathogens are suspected.[1] The primary concern is that prolongation of clearance of pathogens from the intestinal tract could worsen the severity of the illness. However, in patients who are not critically ill with bacillary dysentery, loperamide was not harmful when administered with antimicrobials to which the infecting pathogen was susceptible.[11]

BISMUTH SUBSALICYLATE

Bismuth subsalicylate's (BSS) antidiarrheal properties comprise antisecretory, adsorbent, and antimicrobial properties.[12] Problems with BSS include the inconvenience of dosing four times per day and adverse effects such as darkening of the tongue and stools, possible tinnitus, and GI bleeding risk secondary to its high salicylate component and absorption. Each recommended antidiarrheal dose of BSS of 526 mg contains 263 mg of salicylate, and this needs to be considered in patients already taking salicylate products.

PROBIOTICS

There has been growing interest in probiotic supplementation and its effect on intestinal microbiology. Probiotics are defined as live microorganisms that, when administered in adequate amounts, confer health benefits on the host (eg, restoring normal intestinal flora as a natural defense against intestinal colonization with pathogens and inhibiting the action of microbial toxins).[13] They are not regulated in the United States or Europe in a manner similar to that of pharmaceutical agents. The most commonly available and studied probiotics include the *Lactobacillus* and *Bifidobacterium* genera as well as *Lactococcus* species, and the yeast, *Saccharomyces boulardii.* The variability of the probiotic formulations and the inconsistent analytic rigor of the studies with varying methodologies and clinical end points have led to the lack of

definitive indication for probiotics.[13] Currently, the American Gastrointestinal Association recommends against the routine use in children with acute infectious diarrhea,[14] whereas other associations recommend probiotics for this indication.[7],[15] Probiotics are generally safe in healthy adults, but their use has been associated with a higher risk of infection in young infants and neonates with very low birth weight, critically ill adults and infants, and immunosuppressed individuals.[15]

ANTIMICROBIALS

In selected cases, antimicrobials are prescribed to decrease the duration and the severity of diarrheal illnesses, to prevent the progression to invasive infection, and to prevent person-to-person transmission of pathogens. Antimicrobials are generally recommended for the severely ill, for patients with conditions compromising normal enteric defenses, for immunocompromised patients, and for the treatment of extraintestinal infection.[5]

Ongoing surveillance of antimicrobial resistance is important to guide treatment recommendations. Extensively used in the past and resulting in widespread resistance to common enteropathogens, trimethoprim–sulfamethoxazole (TMP-SMX), the aminopenicillins, nalidixic acid, and tetracyclines are unsuitable empiric choices for the treatment of many enteropathogens. Depending on the circumstances surrounding the diarrheal illness, including where the pathogen was acquired (eg, domestic vs travel related), age, and allergy history of the patient, commonly recommended antimicrobials include selected third-generation cephalosporins (eg, ceftriaxone or cefotaxime), azithromycin, rifaximin, fluoroquinolones, and others.[5]

The fluoroquinolones, although still recommended because of their efficacy against susceptible organisms[5] and their availability as oral formulations, must be used cautiously because common enteropathogens, for example, *Shigella*, *Salmonella*, and *Campylobacter* species, are frequently fluoroquinolone resistant.[16] Another consideration with using fluoroquinolones is that they are not U.S. Food and Drug Administration (FDA) approved for use in

children because lesions on cartilage tissue have been reported in juvenile animals. Nevertheless, because of the emergence of multidrug-resistant (MDR) enteropathogens in some geographic areas, clinical trials using fluoroquinolones in children have been performed,[17] and the available data suggest that a short course of these agents is safe. Finally, all antimicrobial use should be limited to instances where their benefits outweigh their risks for adverse effects and furthering antimicrobial resistance.

Prevention

Good personal hygiene along with proper food handling, cooking, and storage are essential to prevent the spread of enteropathogens. When visiting areas with inadequate facilities for the disposal of sewage, travelers should follow the rule, "boil it, cook it, peel it, or forget it." Effective vaccines are available to prevent typhoid fever, rotavirus, and cholera.[1] To prevent spread to other individuals, people with diarrhea who attend or work in child care, long-term care centers, patient care, food service, or recreational water venues should follow local public health guidance and public health reporting requirements.[7]

EVALUATION AND TREATMENT OF PATIENTS WITH INFECTIOUS DIARRHEA

CASE 69-1

Question 1: B.K. is a 78-year-old male presenting to his physician with a diarrheal illness for 1 day. His illness began with vomiting, followed by abdominal pain, nausea, and watery, nonbloody diarrhea. Despite not feeling well, he is able to drink fruit juices. B.K.'s history of present illness is significant for eating a potato salad at a picnic, and he has since learned that other picnic guests are experiencing a similar illness. B.K. has no significant medical history. He denies recent hospitalization, contact with small children, recent travel, or recent use of antimicrobials. On physical examination, B.K. is alert and oriented,

afebrile, and has stable vital signs. The remainder of his examination is significant for decreased skin turgor and dry mucous membranes.

What is your general approach to the management of B.K.'s diarrheal illness?

Because infectious diarrhea is typically a self-limiting illness, patients may never seek medical attention, and, in many cases, replacement of fluids and electrolytes is all that is required. In general, medical evaluation is warranted for patients with profuse watery diarrhea with dehydration, bloody stools, temperature >101.3 °F (38.5 °C), or illness of >48 hours' duration. Other persons requiring medical evaluation include patients older than age 50 years with severe abdominal pain and immunocompromised patients (eg, those with acquired immunodeficiency syndrome, organ transplant recipients, or patients being treated with cancer chemotherapies). Noninfectious causes for the illness such as medications (eg, laxatives), inflammatory bowel disease, consumption of poorly absorbable carbohydrates (eg, sugarless candies or chewing gum), or malabsorption syndromes should also be considered.[8]

Case 69-1, Question 2: What rehydration plan would you recommend for B.K.?

B.K.'s physical examination is significant for decreased skin turgor and dry mucous membranes, findings consistent with mild-to-moderate volume depletion.[18] Given that B.K. has stable vital signs, and is tolerating oral liquids, oral beverages containing glucose (eg, lemonades, sweet sodas, or fruit juices) or soups rich in electrolytes are appropriate.[19] In developing countries, reductions in dehydration-related mortality are attributed to the utilization of oral replacement therapy solutions containing optimal concentrations of sodium, potassium, chloride, bicarbonate, and glucose; the glucose content of these solutions is responsible for accelerating the absorption of sodium.[7]

IV replacement therapy is warranted for severe dehydration—characterized by lethargy; very sunken and dry eyes; a very dry tongue and mouth; poor skin turgor; a pulse that is fast, weak, or

nonpalpable; poor urine output; and low blood pressure or for persons with intestinal ileus or who are unable to drink on their own.[18]

CLINICAL PRESENTATION

CASE 69-1, QUESTION 3: How does B.K.'s clinical presentation as a noninflammatory versus inflammatory diarrheal illness help guide further treatment?

Classifying diarrheal syndromes as either a noninflammatory (watery diarrhea) or an inflammatory (bloody diarrhea, dysentery) illness provides a basis for predicting the most likely microbial cause for the intestinal illness.[1]

B.K.'s history of present illness and clinical presentation are consistent with a noninflammatory diarrheal illness. Voluminous, watery, nonbloody diarrhea is characteristic of pathogens targeting the small bowel (responsible for absorption of most fluids entering the GI tract), and it is a consequence of bacterial enterotoxins that promote the secretion of water and electrolytes into the intestinal lumen or of viruses infecting and damaging the absorptive villus tips.[9] Noninflammatory diarrheas are typically caused by viruses (eg, rotaviruses and noroviruses), bacteria (eg, *Staphylococcus aureus*, *Bacillus cereus*, and *C. perfringens)*, or parasites (eg, *Cryptosporidium parvum* and *Giardia lamblia*).[1] As with B.K., patients with noninflammatory diarrheal illnesses are not usually severely ill, are afebrile, and without significant abdominal pain[3],[9]; most patients require only supportive therapies.

In contrast, inflammatory diarrheas are generally a more severe illness characterized by diarrhea (with or without dysentery), abdominal pain, and fever.[3] Pathogens targeting the distal small bowel and colon disrupt the epithelial barrier, causing the bloody or mucoid stools.[3] The clinical manifestations are a consequence of the production of cytotoxins (eg, as produced by *C. difficile*, Shiga toxin–

producing *E. coli*, and enteroaggregative *E. coli*), or of the pathogen's ability to invade the intestinal mucosa (eg, *Campylobacter jejuni*, *Shigella* species, and *Salmonella* species).[20] In addition to supportive therapies, selected persons with inflammatory diarrheal illnesses may benefit from antimicrobial therapy directed at the causative pathogen.

VIRAL GASTROENTERITIS

Clinical Presentation and Treatment

CASE 69-1, QUESTION 4: With B.K.'s history of dining at the same restaurant as other patrons having a similar illness, the physician calls the local Health Department to find out if similar illnesses are being reported throughout the city. The physician is informed that an outbreak of norovirus (previously called Norwalk-like virus) gastroenteritis was confirmed at the restaurant where B.K. had dined. Why is B.K.'s history of present illness and clinical presentation consistent with the presumptive diagnosis of viral gastroenteritis, specifically the norovirus? What supportive therapies are recommended?

Noroviruses are responsible for major outbreaks of foodborne viral illnesses in both adults and children, usually in association with restaurants, schools, day care centers, and cruise ships. The virus is spread by eating contaminated foods (eg salads, sandwiches), inadequately cooked clams and oysters harvested from contaminated waters, by person-to-person contact, or by exposure to contaminated recreational waters.[21] As with B.K., within 12 to 48 hours of exposure to the virus, patients report nausea, vomiting, diarrhea, and abdominal cramps. B.K. will likely experience a mild intestinal illness lasting 1 to 3 days. Supportive therapies to correct fluid and electrolyte losses and to replace ongoing losses are the mainstay of treatment for viral gastroenteritis. Preventing future outbreaks will require the restaurant to ensure proper food-handling practices.[21]

Other common causes of viral gastroenteritis are rotaviruses and astroviruses that are responsible for 30% to 60% of all cases of severe, watery diarrhea in children. After an incubation period of 1 to 3 days, patients experience fever, vomiting, and nonbloody, watery diarrhea; otherwise healthy persons are typically ill for 5 to 7 days.

In the United States, two oral rotavirus vaccines are available for the prevention of rotavirus gastroenteritis in infants and children, a pentavalent (three-dose series) and a monovalent (two-dose series). Vaccine effectiveness in high- and upper-middle-income countries ranges from 79% to 100%, with the benefit of vaccination outweighing vaccine risks, for example, intussusception (when a part of the intestine folds into another adjacent part of the intestine, referred to as *telescoping*, which can lead to intestinal obstruction).[22] Because rotaviruses are spread by the fecal–oral route, proper handwashing and disposal of contaminated items are essential to limit the spread of infection.

VIBRIO SPECIES

Vibrio species are curved gram-negative rods whose natural habitats are the environmental waters throughout the world. *V. cholerae* 01 and 0139 are noninvasive enteropathogens responsible for epidemic cholera in humans. The ongoing seventh cholera pandemic began in 1961, subsequently spreading through Asia to Africa, Europe, and Latin America.[7] Prevention of cholera relies on the provision of safe drinking water and adequate sanitation. Cholera vaccines are not routinely incorporated into cholera control efforts, in part related to financial and logistical reasons.[7] Noncholera *Vibrio* species (eg, *V. parahaemolyticus*) do not possess the virulence factors required to cause epidemic cholera but do cause gastroenteritis, wound infections, and, in susceptible hosts, fulminant sepsis.[23] A live-attenuated, oral cholera vaccine is available in the United States for adults ages 18 to 64 who are traveling to endemic areas.[24]

Vibrio cholerae

RISK FACTORS AND CLINICAL PRESENTATION

CASE 69-2

QUESTION 1: M.M. is a 50-year-old male hospitalized for severe watery diarrhea, vomiting, muscle cramping with weakness, and confusion, notably unable to recognize his family members. His history of present illness is significant for returning 1 day ago from Haiti where he visited his relatives, several of whom were recovering from diarrheal illnesses caused by *V. cholerae*. Approximately 24 hours before admission, he noted the onset of watery diarrhea and immediately began drinking the oral rehydrating solution remaining from his trip to Haiti. However, over the past several hours he has been unable to drink on his own, and his family noticed "white flecks" in his stools. M.M. lives in Florida, and his past medical history is significant for peptic ulcer disease for which he takes a proton-pump inhibitor.

In the emergency department (ED), M.M.'s vital signs are as follows: afebrile, blood pressure is 70/40 mm Hg, and heart rate is 130 beats/minute. Physical examination reveals a severely ill-appearing male with altered mental status, sunken eyes, poor skin turgor, and dry mucous membranes. The physician's assessment is severe dehydration because of massive diarrhea, most likely caused by *V. cholerae*.

What are his risk factors for cholera and why is his clinical presentation consistent with this diagnosis?

Risk factors

M.M. has two risk factors to explain his presumed diagnosis of cholera.[25] In developed countries, cholera has been virtually eliminated because of water and sewage treatment systems. However, sporadic cases, similar to M.M.'s, occur in travelers returning from areas where cholera is epidemic or endemic, or from the consumption of contaminated and undercooked seafood (eg, improperly preserved fish, raw oysters, and shellfish) from the waters off the Gulf Coast states or imported from endemic areas.[26] Second, M.M.'s daily use of a proton-pump inhibitor reduces his stomach's acidity, thus allowing the acid-susceptible *V. cholerae* to pass from the stomach into the small intestine.[7]

Clinical presentation

Cholera epidemics are caused by toxin-producing strains of *V. cholerae* 01 or 0139.[7] The characteristic voluminous, watery, and colorless stools with "white flecks" of mucus (referred to as rice-water stools because of their similarity to the appearance of water after washing rice) are caused by the cholera toxin that promotes the intestinal secretion of fluids and electrolytes.[7]

The severity of cholera and likelihood of infection is influenced by host factors and the setting in which it occurs.[7] Severe disease is more common in previously unexposed persons such as M.M. who are immunologically naive (eg, epidemic cholera), whereas less severe disease occurs in areas where cholera is endemic.[7] Following ingestion of contaminated foods, a watery diarrheal illness begins within 18 hours to 5 days and may progress to life-threatening dehydration.[7]

TREATMENT

Case 69-2, Question 2: What are the signs and symptoms suggesting that M.M. is severely dehydrated, and how should his dehydration be treated?

M.M. is one of the 2% to 5% of persons with *V. cholerae* infection who experience severe dehydration (≥10% dehydration), losing up to 1 L/hour of fluid, and whose condition may, within hours, progress to hypovolemic shock and death.[7] M.M. shows signs of severe dehydration as manifested by his altered mental status, sunken eyes, poor skin turgor, dry mucous membranes, low blood pressure, and increased heart rate. Acidosis may occur as a result of massive bicarbonate losses through diarrheal stools, and it may be exacerbated by lactic acidosis from shock and hypovolemic renal failure.[7] M.M. should receive vigorous IV hydration with lactated Ringer solution to replace the large quantities of sodium, potassium, and bicarbonate lost through his watery stools; his muscle weakness could be attributed to depletion of electrolytes, specifically potassium

and calcium.[7] Monitoring of blood pressure and normalization of heart rate are critical interventions.

Once M.M. is able to drink fluids, oral hydration can be started, even with ongoing IV hydration.[7] Oral rehydration solutions can be made by mixing together 1/2 tsp salt, 6 tsp sugar, and 1 L of safe water.[7]

CASE 69-2, QUESTION 3: Would M.M. benefit from the administration of antimicrobials, and what antimicrobial treatment options are available?

Antimicrobials are recommended for patients with moderate-to-severe dehydration from cholera infection.[7] Effective antimicrobial therapy decreases the volume of diarrheal losses, reduces the volume of stool, and reduces the period of shedding infectious organisms.[7] Antimicrobials should be administered after the initial fluid deficit has been corrected and, if applicable, after vomiting has resolved.[7]

Antimicrobials

If susceptible, the following single- and multiple-dose regimens are effective treatments for *V. cholerae*; single-dose regimens are preferred because of their ease of administration, and compared to multiple doses of erythromycin, they are better tolerated.[7],[27]

- Adults: doxycycline 300 mg PO × 1 dose, or azithromycin 1 g PO × 1 dose, or ciprofloxacin 500 mg PO twice a day × 3 days
- Children: ciprofloxacin 15 mg/kg/dose PO twice a day × 3 days, or azithromycin 20 mg/kg PO × 1 dose. Pediatric doses should not exceed maximum adult doses.

For M.M., a single 300-mg PO dose of doxycycline is a good empiric choice because the strain of *V. cholerae* circulating in Haiti is currently susceptible to tetracycline (indicative of susceptibility to doxycycline).[28] Empiric ciprofloxacin is not recommended because the circulating strain in Haiti has reduced susceptibility to ciprofloxacin.[29] In addition, until M.M. has recovered from this

cholera infection, he should refrain from taking his proton-pump inhibitor because it reduces his stomach's acidity, allowing for the acid-susceptible *V. cholerae* to pass from the stomach to the small intestine.

Vibrio parahaemolyticus

CLINICAL PRESENTATION

CASE 69-3

QUESTION 1: C.T. is a 45-year-old male presenting to his physician with 1 day of nonbloody, watery diarrhea. Two days before his illness, he ate raw oysters at a restaurant specializing in fresh local seafood. C.T. lives along the coast of Florida and has no significant medical history. His physical examination reveals no evidence of dehydration.

Why is C.T.'s history of present illness and clinical presentation consistent with noncholera *Vibrio* gastroenteritis?

A key piece of information from C.T.'s history of present illness consistent with the presumptive diagnosis of noncholera *Vibrio* gastroenteritis is the consumption of raw oysters harvested from the coastal areas of Florida, where *V. parahaemolyticus* species have been identified. Diarrhea, abdominal cramps, nausea, vomiting, and fever begin after a median incubation period of 17 hours (range, 4–90 hours); bloody diarrhea occurs in 9% to 29% of cases.[23]

TREATMENT

CASE 69-3, QUESTION 2: Should a course of antibiotics be prescribed for C.T.?

In otherwise healthy adults such as C.T., *V. parahaemolyticus* gastroenteritis is usually a mild, self-limiting illness lasting for a median of 2 to 6 days.[23] There are no data to support the benefit of antibiotics in this setting, although patients with diarrhea lasting >5 days may benefit from treatment with tetracycline or a

fluoroquinolone; doxycycline 100 mg PO every 12 hours and ceftriaxone have also been recommended.[7,23]

Individuals with liver disease or alcoholism are at risk for severe *Vibrio* infections including bacteremia[23]; such individuals should avoid eating raw or undercooked shellfish, and avoid exposure of open wounds to seawater especially during the warmer months when water temperatures favor the growth of *Vibrio* species. Infectious diarrhea caused by *Vibrio* species should be reported to local and/or national reporting mechanisms.[7]

STAPHYLOCOCCUS AUREUS, BACILLUS CEREUS, AND *CLOSTRIDIUM PERFRINGENS*

S. aureus, *B. cereus*, and *C. perfringens* are important causes of toxin-mediated foodborne illnesses. GI symptoms typically begin within 24 hours of the ingestion of contaminated foods, which is in contrast to the longer incubation periods for illnesses caused by *Salmonella*, *Shigella*, and *Campylobacter* species. *B. cereus* causes two different intestinal syndromes: the short-incubation disease characterized by vomiting and a long-incubation disease characterized by a diarrheal illness.[1,30]

Clinical Presentation and Treatment

CASE 69-4

QUESTION 1: S.A. is an otherwise healthy 23-year-old college student who presents to the Student Health Center with an acute GI illness after eating at the school cafeteria. S.A. recalled eating a salad and cream-filled pastries and stated that within 3 hours she felt nauseous and began vomiting.

Why is S.A.'s history of present illness and clinical presentation consistent with food poisoning caused by *S. aureus* or *B. cereus*?

Foodborne illnesses are often grouped by their usual incubation period: <6 hours, 8 to 16 hours, and >16 hours.[30] The rapid onset (within 6 hours) of S.A.'s intestinal symptoms after eating suggests the illness is caused by preformed toxins, such as those produced by *S. aureus* or *B. cereus* (short-incubation disease form, emetic syndrome). Diarrhea and abdominal cramps may also occur. Although cooking kills the toxin-producing bacteria, it does not destroy toxin that has already been produced. Foods implicated in staphylococcal food poisoning include salads, cream-filled pastries, and meats, whereas foods implicated in *B. cereus* food poisoning generally include fried rice, dried foods, and dairy products.[30]

CASE 69-5

QUESTION 1: C.P. is also an otherwise healthy 22-year-old college student presenting to the same Student Health Center as S.A. (see Case 69-4) with an acute GI illness. C.P. recalled having lunch at the cafeteria, selecting a fish and poultry meal. Approximately 10 hours after eating, she experienced diarrhea and abdominal cramps.

Why is C.P.'s history of present illness and clinical presentation consistent with food poisoning caused by *C. perfringens* or *B. cereus*? Should empiric antibiotics be prescribed to either of these students?

In contrast to S.A., the longer incubation period before the onset of symptoms is consistent with illness caused by *C. perfringens* or *B. cereus* (long-incubation disease form, diarrheal syndrome). These bacteria are associated with an incubation period of 8 to 16 hours and symptoms of diarrhea and abdominal cramps; vomiting is not a prominent symptom in these illnesses.[30]

C. perfringens or *B. cereus* (long-incubation disease) produce heat-labile toxins after the ingestion of contaminated foods, explaining the longer incubation period compared with illness caused by the ingestion of preformed toxins. Foods implicated in *C. perfringens* food poisoning include improperly stored beef, fish, poultry dishes, pasta salads, and dairy products, whereas foods implicated in long-incubation *B. cereus* food poisoning include meats, vanilla sauce, cream-filled baked goods, and salads.[30]

Foodborne illnesses caused by these toxin-producing bacteria usually resolve within 24 hours; therefore, antibiotic therapy is not indicated for either student.

CRYPTOSPORIDIUM PARVUM

The protozoan parasite *C. parvum* is an important cause of human intestinal illness in both healthy and immunocompromised persons.[31] The role of antiprotozoal agents and the clinical response to antiprotozoal therapy depends on the competence of the host's immune system.

Clinical Presentation

CASE 69-6

QUESTION 1: C.K. is a 35-year-old, previously healthy male presenting to his physician with 15 days of watery diarrhea and a 5-pound (2.27-kg) weight loss. He is concerned that his illness is related to the announcement by the local Health Department notifying the community of an outbreak of cryptosporidiosis from contaminated water supplies.

Why is C.K.'s history of present illness and clinical presentation consistent with cryptosporidiosis? Should antiprotozoal agents be prescribed to treat cryptosporidiosis in otherwise healthy persons such as C.K.?

C.K. is presenting with persistent diarrhea, that is, diarrhea lasting >14 days. A key finding from C.K.'s history is his exposure to water supplies known to be contaminated with cryptosporidium oocysts; other modes of spreading cryptosporidiosis include animal contact (cattle and sheep) and person-to-person contact.[31] Common microbial causes of persistent watery diarrhea include parasites, such as *Isospora belli*, *Microsporidia*, *G. lamblia*, and *C. parvum*. The spectrum of infection with *C. parvum* ranges from asymptomatic carriage to a persistent, noninflammatory diarrheal illness; vomiting, abdominal cramps, weight loss, and fever may also occur.[31]

Immunocompetent patients such as C.K. can generally expect a self-limiting illness lasting ~2 weeks.[31]

In contrast, in immunocompromised patients (historically in many patients infected with the human immunodeficiency virus [HIV]) and in children, cryptosporidiosis can be a chronic, debilitating, diarrheal illness associated with malnutrition, increased mortality, and long-term cognitive impairment.[32]

Treatment

For immunocompetent hosts with cryptosporidiosis, other than replacement of fluids and electrolytes no specific therapy directed at the organism is generally required. Nitazoxanide, a broad-spectrum antiparasitic, is an FDA-approved treatment for diarrhea caused by *C. parvum and G. lamblia,* including for children older than age 1 year. In adults, a dose of nitazoxanide 500 mg PO twice daily for 3 to 14 days is recommended for the treatment of cryptosporidiosis.[31] The efficacy of nitazoxanide in malnourished children and patients with HIV is limited.

For persons infected with HIV, reconstitution of the immune system with effective antiretroviral therapies is the mainstay of treatment for cryptosporidiosis.[33]

SALMONELLA

Salmonellae are enteric gram-negative bacilli belonging to the *Enterobacteriaceae* family. Widely found in nature colonizing animal hosts including mammals, reptiles, and birds,[34] they are major causes of foodborne illness as a consequence of consuming contaminated foods including poultry and dairy products. Worldwide, the annual incidence of salmonellosis is about 1.3 billion cases, and of the nearly 3 million persons who die,[35] most live in developing areas of the world.

The role of antimicrobials in the management of salmonellosis depends on the clinical syndrome, its severity, and underlying health problems of infected persons. Nontyphoidal salmonellae (eg, *Salmonella typhimurium*, *S. enteritidis*, *S. choleraesuis*, and many others) cause the clinical syndromes of gastroenteritis, asymptomatic carriage in the stool, bacteremia, and localized infection.[36] Typhoidal salmonellae (*S. typhi* and *S. paratyphi* A, B, and C) cause the syndromes of enteric fever (also referred to as typhoid or paratyphoid fever) and chronic carriage.[34]

Nontyphoidal Salmonellosis

CASE 69-7

QUESTION 1: An outbreak of *Salmonella* gastroenteritis being investigated by the Department of Public Health has traced the source of the outbreak to Restaurant A, specifically the popular turkey dinner special.

Anticipating that infected diners with specific clinical syndromes associated with *Salmonella* infection will benefit from antimicrobial treatment, and that antimicrobial-resistant *Salmonella* species are increasingly problematic, the Department of Health has a question for you.

"What antimicrobials are available for the treatment of nontyphoidal salmonellosis?"

DRUG RESISTANCE AND ANTIBIOTIC THERAPY

Trimethoprim–sulfamethoxazole and ampicillin

Until the late 1980s, standard treatments for nontyphoidal *Salmonella* were chloramphenicol, TMP/SMX, or ampicillin. By the early 1990s, widespread multidrug resistance, defined as simultaneous resistance to ampicillin, chloramphenicol, streptomycin, tetracyclines, and sulfonamides, precluded their use as empiric therapies for the treatment of salmonellosis.[34] Depending on the geographic area, rates of MDR *Salmonella* species are as high as 80% in East Asia and southern Europe and 30% to 40% in the United States.[35] As MDR *Salmonella* species remained

susceptible to the fluoroquinolones, these antimicrobials became the agents of choice for the treatment of salmonellosis.[35]

Fluoroquinolones

With the advent of MDR nontyphoidal *Salmonella*, fluoroquinolones were widely prescribed for the empiric treatment of nontyphoidal salmonellosis.[34] During the 1990s, suboptimal clinical responses following treatment with fluoroquinolones were noted when isolates were resistant to nalidixic acid. Both nalidixic acid and the fluoroquinolones are related compounds belonging to the quinolone family of antimicrobials. Because these isolates also displayed elevated ciprofloxacin minimum inhibitory concentrations (MICs) compared to nalidixic acid–susceptible strains (ie, 0.12–1 μg/mL vs ≤0.06 μg/mL, respectively), they were referred to as having decreased ciprofloxacin susceptibility (DCS).[37] Consequently, nalidixic acid resistance became a surrogate marker for isolates with DCS, for which ciprofloxacin was not an optimal antimicrobial choice.

In 2012, the Clinical Laboratory Standards Institute (CLSI) lowered for *Salmonella* species the breakpoint for resistance to ciprofloxacin from >1 to >0.06 μg/mL, to reliably detect *Salmonella* with DCS. The CLSI also recognized that not all laboratories (eg, resource-limited settings) would be able to institute the new ciprofloxacin breakpoints. Nalidixic acid–susceptible isolates with concurrent decreased susceptibility to ciprofloxacin are still uncommon, so CLSI allowed for the continued use of nalidixic acid screening,[37] although prescribers should be made aware of its limitations as a marker for isolates with DCS. Currently, nalidixic acid–resistant nontyphoidal *Salmonella* are prevalent in Asia and increasingly more common in the United States, reportedly 0.4% in 1996 and 2.3% in 2003. Antimicrobial treatment options for nalidixic acid–resistant *Salmonella* include azithromycin and selected third-generation cephalosporins.[37]

β-Lactams

Nontyphoidal Salmonella resistance to ceftriaxone is currently uncommon, but it has been reported worldwide, including in Africa,

Europe, Asia, the Philippines, and the United States,[34] some isolates are also simultaneously resistant to fluoroquinolones.[35],[38] Carbapenems[38] have been successfully used for the treatment of invasive infection (ie, bloodstream infection) caused by ceftriaxone- and ciprofloxacin-resistant *S. choleraesuis*,[39] although carbapenem-resistant *Salmonella* have also been reported.[34]

Azithromycin

Azithromycin displays good in vitro activity against nontyphoidal *S. enterica*[40] and is a recommended treatment for nontyphoidal salmonellosis requiring antimicrobial treatment,[5] including the treatment of nalidixic acid–resistant isolates.

Anticipating recommendations to guide prescribers regarding which diners with salmonellosis should receive antimicrobial therapy, the Department of Health has asked you to address the following question: "Considering a diner's severity of illness and underlying health problems, should antimicrobials be prescribed for diners with the following clinical syndromes: (a) uncomplicated gastroenteritis in the immunocompetent host, (b) asymptomatic stool carriage, or (c) extraintestinal *Salmonella* infection? If appropriate, what specific antimicrobial therapies would you recommend?"

UNCOMPLICATED GASTROENTERITIS IN THE IMMUNOCOMPETENT HOST

Clinical presentation and treatment

CASE 69-8

QUESTION 1: B.B., a 35-year-old, otherwise healthy male presents with a 1-day history of fever, abdominal pain, nausea, vomiting, and nonbloody stools. B.B. has no significant medical history. Physical examination is significant for a non-ill-appearing, febrile male; his presumptive diagnosis is mild, uncomplicated nontyphoidal *Salmonella* gastroenteritis.

Should he receive antimicrobial therapy?

As with B.B., within 6 to 72 hours of ingesting contaminated foods, patients begin experiencing the clinical manifestations of *Salmonella* gastroenteritis including acute onset of fever, diarrhea, and abdominal cramping; in more severe illness, bloody diarrhea and dehydration may occur.

In otherwise healthy individuals with uncomplicated nontyphoidal *Salmonella* gastroenteritis, antimicrobials are not recommended because salmonellosis is typically a self-limiting illness lasting for 2 to 5 days. Antimicrobials do not reduce the duration or severity of illness and may be harmful by placing patients at risk for adverse drug reactions, prolonging the asymptomatic carriage of salmonellae, and promoting the emergence of antimicrobial-resistant bacteria.[36],[41] Most individuals such as B.B. will only require replacement of lost fluids and electrolytes.

ASYMPTOMATIC STOOL CARRIAGE

Clinical presentation and treatment

CASE 69-8, QUESTION 2: Three weeks after resolution of B.B.'s episode of *Salmonella* gastroenteritis, follow-up testing reveals *Salmonella* bacteria from his stool, despite remaining asymptomatic. Should antimicrobials be prescribed to eliminate B.B.'s intestinal carriage of nontyphoidal *Salmonella*?

Antimicrobials should not be prescribed to eliminate asymptomatic intestinal carriage of nontyphoidal *Salmonella*.[20] Outbreaks related to known carriers are rare, so proper hand hygiene remains the mainstay of prevention.[7] A randomized, double-blind trial in healthy, asymptomatic adults from areas where nontyphoidal *Salmonella* infection is endemic found that neither norfloxacin nor azithromycin was better than placebo in eradicating intestinal carriage of *Salmonella* species.[20] The median duration of fecal shedding of nontyphoidal *Salmonella* is about 1 month in adults and 7 weeks in

children younger than 5 years of age.[42] Some health departments may require food handlers to have negative stool cultures before resuming work, so in these cases, treatment may be considered.[7]

GASTROENTERITIS IN PATIENTS AT RISK FOR EXTRAINTESTINAL SALMONELLA INFECTION

Clinical presentation and treatment

CASE 69-9

Question 1: W.M., a 50-year-old male with a past medical history significant for a recently diagnosed malignancy, presents with a 1-day history of fever, severe abdominal pain, nausea, vomiting, and nonbloody stools. One day before the onset of these symptoms, he ate cream-filled pastries from a bakery that has since been closed by the Department of Health because of its association with an ongoing outbreak of *Salmonella* gastroenteritis.

Should antimicrobials be prescribed for his presumed diagnosis of *Salmonella* gastroenteritis, and, if so, what would you recommend?

Antimicrobials are indicated for patients at risk for developing extraintestinal *Salmonella* infection such as persons with malignancy (such as W.M.), diabetes, rheumatologic disorders, HIV infection,[7],[35] persons receiving immunosuppressive therapies, very young age, low gastric pH (eg, as in infancy, pernicious anemia, or medication-induced), severe infection,[36] and persons older than age 50 years who may have atherosclerotic lesions that could become hematogenously infected.[43] Overall, <5% of patients with nontyphoidal *Salmonella* gastroenteritis become bacteremic, although infection with some serotypes, for example, *S. choleraesuis* and *S. dublin* are more likely to cause bloodstream infection.[36] Once in the bloodstream, extraintestinal complications include osteomyelitis, septic arthritis, meningitis, or infectious endarteritis. Lastly, antimicrobials have been used when rapid interruption of fecal excretion of organisms is needed to control outbreaks of salmonellosis in institutionalized persons.[43]

For patients at risk for extraintestinal infection or with severe diarrhea, antimicrobial options include fluoroquinolone (eg,

levofloxacin 500 mg PO once daily) for 7 to 10 days, azithromycin 500 mg PO once daily for 7 days, or parenteral ceftriaxone 1 to 2 g daily for 7 to 10 days (14 days is recommended for immunocompromised patients).[5]

EXTRAINTESTINAL SALMONELLA INFECTION

Clinical presentation and treatment

CASE 69-10

QUESTION 1: B.T., an "ill-appearing" 70-year-old male with a history significant for eating the same cream-filled pastries as W.M. (see Case 69-9, Question 1) is hospitalized for severe abdominal pain, bloody diarrhea, new-onset right hip pain, high fever, and low blood pressure. His past surgical history is significant for a right hip prosthesis.

Would B.T. benefit from antibiotic therapy, and, if so, what would you recommend?

B.T. is presenting with signs and symptoms of *Salmonella* gastroenteritis, bacteremia (fever, low blood pressure), and possible localized infection of his right hip prosthesis (new-onset hip pain).

Treatment of *Salmonella* bacteremia is generally successful after 10 to 14 days of antimicrobial therapy.[5,35] If infection of B.T.'s hip prosthesis is confirmed, surgery may be required to cure his infection.[42] Recommended treatment durations for extraintestinal nontyphoidal salmonellosis are available.[43]

Considering the antimicrobial resistance patterns from where the *Salmonella* infection was acquired (eg, travel history), prior antimicrobial therapy, and site of infection, empiric therapy options until susceptibilities are available include selected IV third-generation cephalosporins (eg, ceftriaxone 1 g IV every 24 hours, cefotaxime 1 g IV every 8 hours),[44] an IV or PO fluoroquinolone (eg, ciprofloxacin 400 mg IV every 12 hours, ciprofloxacin 500–750 mg PO every 12 hours, levofloxacin 750 mg IV or PO every 24 hours), or the combination of a third-generation cephalosporin with a fluoroquinolone.[43] For patients who are bacteremic, some experts prefer the IV route of administration,[43] particularly until the patient

has stabilized,[35] whereas other experts recommend either the IV or oral route of administration.[44]

Typhoidal Salmonellosis—Typhoid Fever (Enteric Fever)

CLINICAL PRESENTATION

CASE 69-11

Question 1: B.C. is a 49-year-old obese female, presenting to the ED with a 1-week history of fever, confusion and delirium, severe abdominal pain, headache, anorexia, and diarrhea and, for the past 1 day, a red rash on her chest. Her history of present illness is significant for returning 10 days ago from travel to the Indian subcontinent where she stayed with relatives, some of whom were recovering from typhoid fever. B.C.'s medical history is significant for gallstones. She lives in California with her husband. Admission vital signs show a temperature of 101 °F (38.33 °C), a heart rate of 60 beats/minute, and a stable blood pressure. Physical examination is significant for an unstable appearance, a red rash on her chest, splenomegaly, and hepatomegaly. Laboratory tests include the following: white blood cell (WBC) count is 3.0 × 10^6/μL, liver function tests are mildly elevated, and the results of two sets of blood cultures are pending. B.C. is given the presumptive diagnosis of severe enteric fever and encephalopathy most likely attributable to *S. typhi*.

Why is her history of present illness, clinical presentation, and laboratory results consistent with this diagnosis?

A key piece of information from B.C.'s history of present illness supporting the diagnosis of typhoid fever is her recent travel to the Indian subcontinent, where typhoid fever is endemic, and her contact with relatives recovering from this infection. Other developing countries with endemic typhoid fever include Southeast Asia, Africa, and Latin America.[45] In developed countries, enteric fever is a sporadic disease occurring mainly in travelers returning from areas where the disease is endemic; in the United States, 85% of cases of typhoid fever are travel related.[46]

B.C.'s clinical presentation and laboratory findings are classic for enteric fever. During the 7- to 14-day incubation period,[45]

salmonellae multiply within macrophages and monocytes, and systemic manifestations of infection appear after the release of bacteria into the bloodstream. Patients usually present with fever, abdominal pain, anorexia, diarrhea or constipation, headache, dry cough, splenomegaly, and hepatomegaly, whereas severe illness is characterized by concomitant GI bleeding, encephalopathy, and shock. Bacteremia may be followed by localized infection to the liver, spleen, bone marrow, gallbladder, and Peyer patches of the terminal ileum.[45] Laboratory abnormalities consistent with typhoid fever include B.C.'s low WBC count and mildly elevated liver function test results.[34]

TREATMENT

Case 69-11, Question 2: Would B.C. benefit from a course of antimicrobials to treat her presumptive diagnosis of typhoid fever? If so, what options are available?

B.C. would benefit from effective antimicrobial treatment for typhoid fever in the following ways: (a) shortening the resolution of fever from 3 to 4 weeks to 3 to 5 days,[47] with clearing of all symptoms within 7 to 10 days,[48] (b) decreasing mortality from usually 5% to 10% to <1%,[34] (c) eradicating fecal shedding of *S. typhi*, thereby limiting further spread of infection,[48] and (d) preventing recurrence of the infection. Most cases of typhoid fever are effectively treated with oral antimicrobials; IV therapy is reserved for severely ill patients or patients with persistent vomiting and severe diarrhea.[45]

Fluoroquinolones

Short-treatment courses (<5 days) of oral fluoroquinolones were once as effective or better than previously used treatments (eg, TMP-SMX, ampicillin, or chloramphenicol) for *S. typhi*.[49] By the late 1990s, short-course fluoroquinolone therapies used in parts of Asia were associated with clinical failures in up to 50% of patients.[46]

Microbiologic evaluation revealed these isolates were resistant to nalidixic acid and had higher ciprofloxacin MICs (0.125–1 μg/mL) compared to *Salmonella* that was fully susceptible to ciprofloxacin (MICs < 0.12 μg/mL).[50]

In areas with a high prevalence of nalidixic acid–resistant *S. typhi*, alternatives to fluoroquinolones include azithromycin and selected third-generation cephalosporins.

Azithromycin

Azithromycin is effective for patients with mild-to-moderate typhoid fever.[51] Azithromycin (20 mg/kg/day) for 7 days cured >95% of children with uncomplicated typhoid fever in Vietnam where 96% of *S. typhi* are nalidixic acid resistant; fever clearance time was 106 hours, and there were no recurrences.[17] In contrast, lower azithromycin doses (10 mg/kg/day) in the setting of nalidixic acid resistance are associated with lower cure rates (82%).[52] The identification of azithromycin-resistant *S. typhi*[53] and nonresponse to azithromycin is a current concern.[54]

β-Lactams, carbapenems, and tigecycline

Cefixime, an oral third-generation cephalosporin, is variably effective in the treatment of typhoid fever. Failure rates range from 4% to 27%[53] and some experts do not recommend its use for the treatment of typhoid fever.[46] The lower clinical response to cefixime may be related to the poor intracellular penetration of the β-lactam because the intracellular compartment is the primary site of *S. typhi* colonization.[55]

Ceftriaxone, an intravenous (IV) third-generation cephalosporin, is recommended for the treatment of severe typhoid fever[47] with the caveat that longer treatment courses are recommended to prevent recurrence of infection. In patients with bacteremia caused by ceftriaxone-susceptible isolates, recurrence of infection was higher among patients treated with a 7-day course of ceftriaxone versus azithromycin, 14% versus 0%, respectively.[56] No recurrences were reported when a longer course (14 days) of ceftriaxone was used for

infection caused by MDR *S. typhi*.[57] Patients treated with ceftriaxone may remain febrile for as long as 10 days.[58] Ceftriaxone-resistant *S. typhi* have been reported in India, the Philippines, China, the United States, and elsewhere.[59] Potential alternatives to ceftriaxone include carbapenems (imipenem, meropenem, and ertapenem) and tigecycline, although clinical data are lacking.[51]

TREATMENT—SEVERE VERSUS UNCOMPLICATED TYPHOID FEVER

Case 69-11, Question 3: What specific empiric antibiotic regimen would you recommend for the treatment of B.C.'s complicated (severe) typhoid fever? How would her treatment differ if she had uncomplicated typhoid fever?

For complicated typhoid fever, empiric therapy with ceftriaxone is recommended.[60] Once susceptibility data are available, treatment options include 10 to 14 days of ceftriaxone (1–2 g IV once daily) continued for at least 7 days after defervescence to minimize the risk for recurrence,[51] or a fluoroquinolone for 10 to 14 days.[47]

Uncomplicated typhoid fever is typically treated in the outpatient setting.[47] Empiric oral regimens include azithromycin 500 mg daily × 5 to 7 days,[47] or a fluoroquinolone (eg, levofloxacin 500 mg once daily or ciprofloxacin 500 mg twice daily) for 7 days.[5] For children, azithromycin or ceftriaxone is recommended.[5]

ADJUNCTIVE TREATMENT

Case 69-11, Question 4: Besides the administration of antibiotics, what adjunctive therapies could benefit B.C. for the treatment of severe typhoid fever?

Enteric encephalopathy, that is, altered mental status, is associated with a mortality rate as high as 56% if effective treatment is not promptly administered.[61] In patients with enteric encephalopathy, retrospective data report improved survival when

appropriate antimicrobial therapy is combined with high-dose dexamethasone (3 mg/kg IV followed by 1 mg/kg every 6 hours IV for eight doses).[61] The exact mechanism of action of dexamethasone in enteric encephalopathy is not known but hypothesized to reduce inflammation.[61]

CASE 69-11, QUESTION 5: Fourteen months after discharge from the hospital, B.C. remains free of symptoms associated with typhoid fever, but follow-up testing reveals that she continues to excrete *S. typhi* in her stools. In addition, their adult son who has dinner with them every Sunday presents to his clinic doctor with fever, headache, and chills, and is confirmed to have uncomplicated typhoid fever. He has no significant past medical history and has no recent travel history. How might her son have acquired typhoid fever? What treatment recommendations can be provided to this family?

Unlike his mother, B.C.'s son has no travel history to an area where typhoid fever is endemic. Instead, he is likely to have contracted typhoid fever from consuming foods prepared by his mother who is now a chronic carrier of *S. typhi*. Most patients with typhoid fever continue to excrete *S. typhi* in their stools for 3 to 4 weeks after recovery from their illness. However, 1% to 3% of persons such as B.C. become chronic carriers who continue to excrete *Salmonella* from stool or urine for >1 year after infection and serve as reservoirs for spreading infection. Unlike for nontyphoidal salmonellae, humans are the only natural host and reservoir for *S. typhi*.[58] B.C.'s risk factor for becoming a chronic carrier is her history of gallstones that allows the sequestration of organisms within her abnormal biliary tract.

CHRONIC TYPHOID CARRIERS

Treatment

CASE 69-11, QUESTION 6: What therapeutic options are available to cure B.C.'s chronic carrier state?

Treatment options for chronic *S. typhi* carriers such as B.C. include a prolonged course of antibiotics, cholecystectomy, or suppressive antimicrobial therapy.[45] Fifty percent to 90% of chronic carriers may be cured after prolonged courses of antibiotics,[62–65] although efficacy may be lessened when anatomic abnormalities (eg, cholelithiasis) are present.[62] Recurrence is usually detected within the first several months of completing antimicrobial therapy[66] but can occur up to 24 months after completing therapy.[67] For susceptible *S. typhi*, curative oral antimicrobial regimens include amoxicillin 2 g three times daily for 28 days,[64] ampicillin 1 g four times daily for 90 days,[63] ampicillin 1.5 g four times daily plus probenecid for 6 weeks,[62] TMP-SMX 160/800 mg twice a day for 3 months,[65] ciprofloxacin 500 to 750 mg twice a day for 3 to 4 weeks,[65–69] or norfloxacin 400 mg twice daily for 4 weeks.[70]

Prevention

Case 69-11, Question 7: B.C.'s sister is planning a trip to the Indian subcontinent and is concerned about acquiring typhoid fever. What can she do to reduce her risk of becoming infected?

The U.S. Centers for Disease Control and Prevention recommends vaccination for travel to areas where the risk for *S. typhi* is increased, including many Asian, African, and Latin American countries.[71] In the United States, two licensed vaccines are available to protect against *S. typhi* but not against *S. paratyphi*. The intramuscular vaccine for persons older than age 2 years is 55% effective in preventing typhoid fever; adverse effects include local pain and swelling, fever, and headache.[71] The oral live-attenuated vaccine Ty21a vaccine (a series of four doses) for persons older than age 6 years is well tolerated, and it affords a protective efficacy rate around 55%. The vaccine series should be completed 1 week before travel.[71] The oral vaccine is a live-attenuated vaccine, and therefore should not be administered to immunocompromised persons. In addition, to ensure full vaccine activity, the live-

attenuated vaccine should not be given until at least 3 days after the last dose of an antimicrobial, and, if possible, antimicrobials should not be initiated within 3 days of the last dose of the oral vaccine; longer intervals should be considered for long-acting agents such as azithromycin.[71]

Finally, because the protective efficacy of available vaccines against *S. typhi* is incomplete and because neither vaccine is licensed to protect against *S. paratyphi*, which in some Asian countries accounts for up to 50% of blood isolates from patients with enteric fever,[72] it is still necessary to reinforce the importance of good hygiene and the avoidance of foods with a high risk of being contaminated with enteropathogens.

SHIGELLA SPECIES

Shigella are gram-negative intracellular bacterial pathogens belonging to the *Enterobacteriaceae* family. They are the most frequent cause of dysentery, which is an inflammatory diarrheal illness characterized by bloody or mucoid stools with abdominal cramps. Of the four *Shigella* species, severe dysentery is most commonly caused by *Shigella dysenteriae* followed by *S. flexneri*, whereas milder illness characterized by watery diarrhea with or without blood is typically caused by *S. sonnei* and *S. boydii*.[73]

Shigellosis—Severe Illness

CLINICAL PRESENTATION

CASE 69-12

QUESTION 1: M.T. is a 60-year-old, ill-appearing male hospitalized for bloody diarrhea and fever. Two days before admission he noted the onset of fever, abdominal cramps, and 6 to 7 nonbloody, watery stools. His diarrhea has since worsened to 10 to 12 small-volume stools with blood and mucus, and he now reports painful straining while passing his stools. His history of present illness is

significant for returning 3 days ago from a business trip to the Indian subcontinent. During the business portion of the trip, he remained at the hotel where all his meals were prepared by hotel staff well trained in the sanitary preparation of foods. However, on the day of his departure, he opted to mingle with local residents to get a first-hand taste of native foods and beverages from street vendors. M.T. lives alone in Florida, has no significant medical history or drug allergies, and takes no medications. On admission, his temperature is 101 °F (38.33 °C) and physical examination reveals a critically ill male with severe abdominal tenderness.

Why is M.T.'s history of present illness and clinical presentation consistent with the diagnosis of dysentery, most likely caused by *S. dysenteriae type 1*?

M.T.'s diagnosis of dysentery, likely caused by *S. dysenteriae type 1*, is consistent with his recent travel to the Indian subcontinent where *S. dysenteriae type 1* is both epidemic and endemic,[73] primarily a consequence of inadequate systems for sewage disposal.[73] M.T. likely became infected from the consumption of contaminated foods or beverages prepared by local street vendors, by person-to-person contact with symptomatic persons with diarrhea, or from asymptomatic persons continuing to excrete shigellae from their stool.[74] As few as 10 to 100 individual shigellae organisms can cause illness[73] in healthy hosts, explaining why shigellosis is a very contagious infection.

Once ingested, virulence factors allow shigellae to evade detection by the immune system and invade colonic and rectal epithelium. Enterotoxin production causes fluid secretion into the intestinal lumen and cytotoxin production causes cell death; both toxins lead to the severe clinical manifestations of shigellosis.[73]

As with M.T., within 24 to 48 hours of ingestion of *Shigella* bacteria, symptoms of dysentery begin and include fever, fatigue, malaise, and anorexia.[74] Watery diarrhea generally precedes dysentery and frequently is the only manifestation of mild infection.[74] Progression to dysentery may follow within hours to days and is characterized by frequent, small-volume, bloody, and mucoid stools; abdominal cramps; and tenesmus that is described as painful straining when passing stools.[74] Hemolytic uremic syndrome (HUS) is a serious complication of shigellosis, occurring in up to 13% of patients with dysentery caused by *S. dysenteriae type 1*. HUS is a

consequence of the production of Shiga toxin 1, most commonly produced by *S. dysenteriae* but also rarely by *S. flexneri*.[73] Longer term health complications of diarrheal illness caused by invasive pathogens such as *Shigella* species, as well as *Salmonella* and *Campylobacter* species, include postinfectious irritable bowel syndrome (PI-IBS)[75] or reactive arthritis.[76]

TREATMENT

Case 69-12, Question 2: Would M.T. benefit from antimicrobials to treat bloody diarrhea and fever (dysentery), presumably caused by *S. dysenteriae type 1*?

M.T. would benefit from antimicrobial therapy for dysentery presumably caused by *S. dysenteriae type 1*: First, effective antimicrobial therapy reduces the average duration of illness from 5 to 7 days to about 3 days[74] and reduces the risk of death and serious infection-related complications. Within 48 hours of starting treatment, M.T. should notice a reduction in stool frequency, volume of bloody stools, and fever. Second, effective antimicrobial therapy quickly reduces the carriage and excretion of shigellae, thus limiting the spread of infection. Despite the benefits of antimicrobial therapy, there has been concern that antimicrobials could increase the risk of developing HUS. However, Bennish et al[77] reported that early administration of effective antimicrobials (ie, within 3–4 days of the onset of dysentery) is associated with a low risk of developing HUS. Supportive management with fluids is imperative with antimicrobial therapy.

Case 69-12, Question 3: What empiric antimicrobial regimens are available for the treatment of shigellosis?

Shigella species are well known for rapidly developing resistance following exposure to antimicrobials; therefore, selection of empiric therapy should be based on local antimicrobial susceptibility

patterns.[73] For information on susceptibility data in the United States, see National Antimicrobial Resistance Monitoring system (NARMS; http://www.cdc.gov/narms).

Antibiotic therapy: fluoroquinolones, azithromycin, β-lactams

During the 1960s to 1980s, ampicillin, TMP-SMX, or nalidixic acid was the standard treatment for shigellosis. During the 1990s, MDR (ie, resistance to ampicillin, TMP-SMX, and chloramphenicol) *Shigella* precluded their empiric use for shigellosis, but because these MDR isolates remained susceptible to fluoroquinolones, these agents became the drugs of choice for this infection.[73] In adults, ciprofloxacin 500 mg PO twice daily for 3 to 5 days is effective against MDR *S. dysenteriae type 1* infection in the setting where all isolates are susceptible to ciprofloxacin and nalidixic acid.[12] With the widespread introduction of fluoroquinolones as the drugs of choice for the treatment of shigellosis, quinolone-resistant shigellae have emerged.[78] Ciprofloxacin resistance in *Shigella* species from Asia and Africa has progressively increased from 0.6% before 2000 to 29.1% during 2007 to 2009.[79] Although the prevalence of ciprofloxacin-resistant *Shigella* remains low (<5%) in Europe and the Americas,[79] international travel is strongly associated with the importation and subsequent circulation, within the United States, of ciprofloxacin-resistant *S. sonnei*[80] and other MDR *Enterobacteriaceae*.[81]

In the setting of epidemic dysentery caused by *S. dysenteriae type 1*, similar clinical outcomes were observed in adults treated with a single 1-g PO dose of azithromycin or multiple doses of ciprofloxacin (500 mg PO twice daily for 3 days). In this study, the mean number of days until resolution of symptoms after starting therapy was similar (2.5 days for azithromycin vs 2.3 days of ciprofloxacin) but only 17% of isolates were nalidixic acid resistant.[82]

In adults with moderate-to-severe shigellosis caused by MDR *Shigella* species, clinical efficacy is similar to that with azithromycin (500 mg PO on day 1, then 250 mg PO daily for 4 days) or ciprofloxacin (500 mg PO every 12 hours for 5 days), 89% versus

82%, respectively ($P > .2$).[83] In a subgroup analysis, a greater proportion of patients infected with *S. dysenteriae type 1* failed therapy with either azithromycin (29%) or ciprofloxacin (17%), compared with patients infected with other *Shigella* species (failure rate of 6% for both antibiotics).[83] Intercontinental spread through sexual transmission of azithromycin-resistant shigellosis and treatment failure following azithromycin therapy has been reported.[84] *S. sonnei* with reduced susceptibility to azithromycin remains susceptible to ceftriaxone,[85] and ceftriaxone has successfully treated a patient with azithromycin-resistant shigellosis failing azithromycin therapy.[86]

The oral third-generation cephalosporin cefixime is unreliable for the treatment of shigellosis, with failures reported in 11% to 47% of patients.[87] Parenteral ceftriaxone and cefotaxime have excellent in vitro activity against *Shigella* species and have been used alone or with amikacin[87] for patients failing ciprofloxacin therapy. Although uncommon, ceftriaxone-resistant *Shigella* have been reported in Asia.[73] Ongoing surveillance to detect changes in antimicrobial susceptibility among *Shigella* species is needed to direct local empiric treatment recommendations.

CASE 69-12, QUESTION 4: Should loperamide be started in patients with dysentery?

The role of antimotility drugs in patients with dysentery has been debated, the concern being that prolonging the clearance of pathogens from the intestinal tract could worsen the severity of illness. However, loperamide (in combination with ciprofloxacin) has been safely used in adults who are not critically ill with bacillary dysentery primarily caused by *Shigella* species, decreasing the number of unformed stools and shortening the duration of diarrhea; fever was not prolonged in these patients.[11] However, the authors stress that all *Shigella* isolates in the study were susceptible to the antimicrobial used (ie, all isolates were susceptible to ciprofloxacin and nalidixic acid) and none of the patients were critically ill; thus, it

would not be prudent to extrapolate the findings from this study to patients who are critically ill such as M.T.[11]

Case 69-12, Question 5: What empiric antimicrobial regimen could be started in patients such as M.T. with severe dysentery, likely caused by *Shigella* species?

Ciprofloxacin, azithromycin, and ceftriaxone are the primary agents used for the treatment of shigellosis,[5,78] although resistance to all of these agents has been reported. In the setting of severe dysentery associated with nausea and vomiting, parenteral ceftriaxone is a reasonable empiric option.[73] Fluoroquinolones are a less desirable option given the widespread prevalence of fluoroquinolone-resistant *Shigella* species in areas including the Indian subcontinent[79] where M.T. likely became infected.

Shigellosis—Mild Illness

CLINICAL PRESENTATION

CASE 69-13

Question 1: F.F. is a 30-year-old, previously healthy female, presenting to her physician with nonbloody, watery diarrhea of 3 days' duration. Her history of present illness is significant for the following: 2 days before the onset of her GI symptoms, she visited her 4-year-old nephew who was recovering from an intestinal illness caused by *S. sonnei* acquired at his day care center. F.F. has no significant medical history. Overall, she feels better compared to the previous day and is afebrile.

How does F.F.'s clinical presentation of shigellosis differ from that of M.T. (see Case 69-12, Question 1)? Should F.F. be treated with antimicrobials for her presumed, mild case of shigellosis?

TREATMENT

Compared to M.T., F.F. is experiencing a much milder, and likely self-limiting case of shigellosis. In industrialized countries, risk factors for shigellosis include settings where individuals are in close contact

such as in child care centers, military barracks, and institutional housing.[74] International travel[80] and sexual transmission in males who have sex with males[84] are other means of spreading shigellosis. Secondary attack rates as high as 40% occur within 1 to 4 days of exposure to the primary case; infected persons may continue to asymptomatically shed *Shigella* in stool following recovery from their illness.

S. sonnei accounts for 90% of shigellosis in developed countries. Because most patients have a mild and self-limiting illness, antimicrobials are not generally required. However, from a public health standpoint, they are often prescribed to shorten the duration of illness to reduce the infectious period.[88] On the other hand, with the emergence of MDR *Shigella* species, some experts favor reserving antimicrobials for only severely ill persons.[89]

Empiric antimicrobial options include a 3-day course of either ciprofloxacin 500 mg PO twice daily or azithromycin 500 mg PO once daily; ceftriaxone can also be used.[89] Clinical improvement may be evident within 24 hours.[73]

PREVENTION

Prevention of shigellosis requires good hygiene, including proper handwashing and reducing fecal–oral exposure during sexual contact.[90] Development of an effective vaccine has been limited by poor vaccine immunogenicity, decreased vaccine protection because of the changing prevalence of infection caused by nonvaccine serotypes, and adverse effects.[73]

CAMPYLOBACTER JEJUNI

Clinical Presentation

CASE 69-14

Question 1: M.U. is a 20-year-old, previously healthy female presenting to the Student Health Center with malaise, fever, diarrhea, abdominal pain, and bloody diarrhea for the past 24 hours. One day before the onset of symptoms, she dined at a restaurant near campus, noting that the chicken she ate was perhaps not thoroughly cooked. She has no significant medical history, no recent travel history, and is a full-time student at a university in the United States. On physical examination, M.U. is not ill appearing. The physician tells her that during the past week several students with GI symptoms similar to hers have been diagnosed with *C. jejuni* gastroenteritis, and all had recently eaten at the same restaurant.

Why is M.U.'s history of present illness and clinical presentation consistent with *Campylobacter* gastroenteritis?

M.U.'s presumptive diagnosis of *Campylobacter* gastroenteritis is consistent with her recent history of eating undercooked chicken at a restaurant associated with an ongoing outbreak of *Campylobacter* gastroenteritis. In industrialized nations, the most important risk factor for acquiring *Campylobacter* infection is the consumption of contaminated undercooked poultry, dairy products, unpasteurized foods, or contaminated water.[91] Prevention of *Campylobacter* infection involves careful food preparation and cooking practices.[92]

Beginning 24 to 72 hours after consumption of contaminated foods, clinical manifestations of *Campylobacter* gastroenteritis typically include diarrhea, fever, and abdominal cramps with either loose and watery or bloody stools.[91] Postinfectious complications of *C. jejuni* gastroenteritis include Guillain–Barré syndrome, reactive arthritis, and PI-IBS; the latter associated with diarrhea lasting >7 days.[91]

Treatment

Case 69-14, Question 2: Would M.U. benefit from antimicrobial therapy to treat her *Campylobacter* gastroenteritis?

Because *C. jejuni* gastroenteritis is typically an acute, self-limiting illness resolving within 3 to 7 days,[93] antibiotic therapy is usually not

necessary.[91] Antibiotics are recommended for patients with symptoms lasting >1 week, high fevers, bloody stools, pregnant females, or immunocompromised hosts.[94] Because M.U.'s clinical presentation includes fever with bloody stools, antimicrobial therapy is warranted. Effective antimicrobial therapy shortens the duration and the severity of illness by a mean of 1.3 days, and it is most beneficial when started within 3 days of the onset of illness.[91]

CASE 69-14, QUESTION 3: What empiric antimicrobial therapies could be initiated to treat M.U.'s presumed case of *C. jejuni* gastroenteritis?

MACROLIDES

Macrolides remain the drugs of choice for the treatment of *Campylobacter* gastroenteritis.[3] Macrolide resistance has remained relatively stable around 5%,[91] but depending on geographic location, higher macrolide resistance has been reported from Eastern Europe and China (5%–11%)[95] and India (22%).[96]

FLUOROQUINOLONES

Once considered the drugs of choice for *Campylobacter* infection, fluoroquinolones are no longer first-line options as a consequence of widespread fluoroquinolone resistance, largely attributed to their use in veterinary medicine and food animals (eg, poultry); the latter practice has since been banned in the United States.[95] Fluoroquinolone-resistant *C. jejuni* exceeds 80% in Spain, Thailand, and Hong Kong, and it is about 50% in selected European Union States.[97] In the United States, the prevalence of ciprofloxacin-resistant *C. jejuni* remained between 20% and 30% from 2007 to 2011.[91,95,98] However, higher quinolone resistance among *Campylobacter* isolates in international travelers returning to the United States compared to nontravel-associated isolates (60% vs 13%)[95] underscores the need to consider local resistance patterns from where infection was acquired when selecting empiric antimicrobial therapy for returning travelers.

Recommended oral treatments for *C. jejuni* gastroenteritis for adults are azithromycin 500 mg once daily for 3 days or erythromycin 500 mg four times daily for 5 days.[5] On the basis of M.U.'s medical history and clinical presentation, empiric therapy with oral azithromycin can be started.

TRAVELERS' DIARRHEA

Of the nearly one billion people traveling each year from industrialized countries to developing areas of the world, ~10% to 60% will experience an acute self-limiting episode of travelers' diarrhea (TD).[16,99] TD is usually viewed from the perspective of individuals originating in high-income countries and traveling to lower and middle-income countries. TD is defined as a disease where patients develop three or more unformed stools per 24 hours plus one additional symptom such as abdominal cramps, tenesmus, nausea, vomiting, fever, fecal urgency, or the passage of bloody or mucoid stools. Often, a diagnosis is made on the clinical presentation and travel history and a microbiologic diagnosis is not made.[16] Long-term postinfectious complications occur in a small proportion of returning travelers.[16] Experts recommend pretravel education focusing on the prevention of TD and instructions for the self-treatment of TD at the onset of illness.[100]

CASE 69-15

QUESTION 1: W.D. and B.D. are healthy 23-year-old females beginning a 2-week backpacking trip through Latin America. Before their departure, both travelers attended a travel clinic where they received instructions to minimize their risk factors for TD and a travel kit including instructions and medications for the self-treatment of TD. On the day of their arrival, both travelers seek out local street vendors, sampling their fresh fruits, vegetables, prepared foods, and unbottled beverages.

On the second day of their vacation, both travelers are not feeling well. W.D. notes only the passing of two to three watery stools without blood and mild nausea. In contrast, B.D. is feeling much worse, noting the passing of six to

seven loose, bloody stools, abdominal cramps, and feeling “feverish.” Neither traveler feels dizzy or thirsty, and both are able to continue drinking unbottled water and juices.

What are their risk factors for TD and why are their clinical presentations consistent with this diagnosis?

Risk Factors

Both travelers have several risk factors for acquiring TD. First, their travel to Latin America, a destination considered “high risk” for TD; other high-risk destinations include South Asia and West/Central Africa.[16] Second, because the highest risk for TD is during the first 2 weeks of travel, their recent arrival to an at-risk destination increases the likelihood of infection; the risk factor for TD lessens during the second (9.9% risk) and third (3.3% risk) weeks of travel.[16] Third is their travel style of eating foods with a high risk of contamination with enteropathogens such as foods from local street vendors and drinking unbottled beverages. Additional high-risk foods include ice cubes, raw milk, unpeeled fruits and vegetables, uncooked foods, moist foods; foods remaining at room temperature for prolonged periods of time, allowing bacteria to multiply or release their enterotoxins[101]; use of acid-inhibiting medications allowing acid-susceptible enteropathogens to pass through to the intestines; and genetic predisposition.[16]

Clinical Presentation

W.D. has symptoms consistent with TD. In travelers, illness typically begins within 24 to 48 hours of consuming fecally contaminated foods. Left untreated, TD is generally a self-limiting illness lasting 4 to 5 days.[16]

Severity of the diarrhea can be classified into three categories[102]:

Mild (acute): diarrhea that is tolerable, is not distressing, and does not interfere with planned activities

Moderate (acute): diarrhea that is distressing or interferes with planned activities

Severe (acute): diarrhea that is incapacitating or completely prevents planned activities; all dysentery (passage of grossly bloody stools) is considered severe.

Persistent: diarrhea lasting ≥2 weeks

General Management

Case 69-15, Question 2: What general approach should W.D. and B.D. take to manage their diarrheal illnesses?

Realizing that their symptoms are consistent with TD, both travelers review their pretravel information for the self-management of TD.

HYDRATION

To replace fluid and electrolyte losses, they should continue to drink only bottled or boiled liquids such as tea, broth, carbonated beverages, and fruit juices.[101] Electrolytes can be replaced by eating salted crackers or similar sources of sodium chloride. For travelers able to drink fluids ad libitum, a modified World Health Organization oral rehydration solution offers no additional benefit over the administration of loperamide alone.[103] Neither traveler has symptoms indicative of significant dehydration such as thirst, dizziness, or altered mental status.

SAFE FOODS—"PEEL IT, BOIL IT, OR FORGET IT"

Travelers should avoid consuming foods with a high risk of contamination with enteropathogens that include raw vegetables and fruits that are not peeled or cooked, food not served steaming hot, and tap water.[104] Instead, they should only eat fruits that they have themselves peeled or that have been adequately washed, and well-cooked foods served steaming hot. Enteropathogens are killed at 100 °C and foods served piping hot at 60 °C are generally safe.[16]

Despite adherence to dietary restrictions and precautions, prevention of TD is not always possible, likely reflecting the difficulty with adhering to sanitary standards for the preparation and serving of foods, the lack of facilities for employees to wash their hands after going to the bathroom, or the lack of screens or windows to prevent flies from contaminating foods.[16]

SELF-TREATMENT OF TRAVELERS' DIARRHEA

Antimotility agents alone provide rapid relief of symptoms but do not cure the infection, whereas antimicrobials alone will cure the infection but symptoms may persist for a longer time.[101] In the appropriate setting, antimotility drugs plus antibiotics provide the fastest relief of diarrheal symptoms.[101] Selection of a self-treatment plan is, in part, based on the traveler's severity of illness and manifestations of their diarrheal illness.

Microbial Etiology, Clinical Manifestations, and Treatment Options

Case 69-15, Question 3: For travelers with the following manifestations of TD, (a) watery diarrhea without blood or fever, (b) bloody diarrhea or fever, or (c) diarrhea while taking chemoprophylaxis, what are the common microbial etiologies, and what treatment options are available to manage these diarrheal syndromes?

The microbial etiology of TD is recognized in 50% to 94% of patients, with bacteria most commonly identified; viruses and parasites are less frequently isolated.[16] For travelers to developing countries, the most common enteropathogen is enterotoxigenic *Escherichia coli* (ETEC), followed by enteroaggregative *Escherichia coli* (EAEC), diffusely adherent *E. coli*, noroviruses, rotaviruses, *Salmonella* species, *C. jejuni*, and *Shigella* species.[16] The likely enteropathogen afflicting individual travelers can in part be predicted by the clinical manifestations of the diarrheal illness and the travel destination information (provided by the Centers for Disease

Control), which is helpful for selecting an appropriate self-treatment plan).[105]

WATERY DIARRHEA WITHOUT FEVER OR BLOODY DIARRHEA

ETEC is suspected in the setting of acute watery diarrhea, especially in travelers to Latin America and the Caribbean (≥35% of reported pathogens), Africa (25%–35% of reported pathogens), and South Asia (15%–25% of reported pathogens).[16] ETEC produces enterotoxins that stimulate the intestinal mucosa to secrete fluid into the gut lumen, leading to diarrheal stools.

Loperamide, diphenoxylate/atropine, bismuth preparations

Loperamide alone can be considered in patients with a mild diarrheal illness, for example, two loose stools and mild symptoms,[106] without fever or bloody stools.[104] Loperamide rapidly relieves diarrheal symptoms, often within >24 hours[104] and is better tolerated than is diphenoxylate/atropine. Mild diarrheal illness may be less likely to be infectious in etiology, but instead because of noninfectious causes such as anxiety, diet changes, and stress.[106] BSS is moderately effective in improving diarrheal symptoms.[16]

Alternatively, travelers on a short and critical trip (eg, business) might consider the addition of an antibiotic. However, the potential adverse consequences of antimicrobial therapy such as the risk of adverse drug events, additional cost, and antimicrobial resistance should also be considered. A recent prospective study reported that depending on the travel destination, the risk factor for a traveler with diarrhea becoming colonized with extended-spectrum β-lactamase–producing *Enterobacteriaceae* was greatest (28%–80%) if an antimicrobial was taken versus if no antibiotic was taken (8%–47%).[81] After returning home, up to 24% of travelers remain colonized at 6 months and 10% remain colonized at 3 years.[81] Consequently, some experts do not recommend antimicrobials for mild-to-moderate disease nor for the prevention of TD.[81]

Antimicrobials alone

Rifaximin, ciprofloxacin or levofloxacin, or azithromycin are recommended for travelers with moderate or severe TD[102],[105] (**Table 69-2**). For travelers to Mexico[107],[108] or Kenya,[109] where ETEC is a frequent cause of TD, a single dose of ciprofloxacin 500 mg, azithromycin 1 g, or levofloxacin 500 mg decreased the median time to passage of the last unformed stool to 22 to 33 hours versus 54 to 66 hours for travelers given placebo.[110] For travelers to Mexico or India, oral rifaximin 200 mg three times daily or ciprofloxacin 500 mg twice daily for 3 days significantly reduced the median time to passage of the last unformed stool to 32 and 29 hours, respectively, versus 66 hours for travelers taking placebo.[111] Rifaximin is not systemically absorbed, is well tolerated, and has a low potential for the development of antibiotic resistance.[112]

Table 69-2
Therapy for Travelers' Diarrhea in Adults

Drug	Treatment
Ciprofloxacin	500 mg PO twice daily or 750 mg PO once daily × 1–3 days[a]
Azithromycin	1000 mg PO in a single dose or 500 mg PO once daily × 3 days
Rifaximin	200 mg PO three times daily × 3 days

PO, orally.

[a]Single dose may be effective. If diarrhea improves 12 to 24 hours after the first dose, the antibiotic can be stopped; otherwise, may continue antibiotic for up to 3 days.

Antimotility drugs plus antimicrobials

The combination of antimotility drugs plus antimicrobials provides the fastest relief of diarrheal symptoms. The antimotility drug quickly acts to reduce the number of stools, whereas the antimicrobial cures the infection.[107] In military personnel stationed in Turkey with TD primarily caused by ETEC, the median time to the passage of the

last unformed stool was shortened to as little as 3 hours in recruits taking loperamide (4 mg PO initially, then 2 mg PO as needed; maximum 16 mg/day) plus either levofloxacin (single 500-mg dose) or azithromycin (single 1-g dose).[113] In otherwise healthy U.S. students at least 18 years old attending school in Mexico, the combination of rifaximin (200 mg PO three times daily for 3 days) plus loperamide (4 mg initially, then 2 mg after each unformed stool) relieved diarrheal symptoms faster (27 ± 4.13 hours) than did rifaximin alone (32.5 ± 4.14 hours) or loperamide alone (69 ± 4.11 hours).[112]

BLOODY DIARRHEA WITH OR WITHOUT FEVER, OR DIARRHEA

Invasive pathogens including *Shigella*, *Campylobacter*, and, less commonly, *Salmonella*, noncholera *Vibrios*, and *Aeromonas* species are suspected in the setting of acute bloody diarrhea with fever. *Campylobacter* species are frequent causes of TD in travelers to Southeast Asia (25%–35% of reported pathogens) and South Asia (15%–25% of reported pathogens).[16]

Antimicrobials alone

A comparative study reported the highest cure rate with a single dose of azithromycin 1 g (96%), followed by 3 days of either azithromycin 500 mg daily (85%) or levofloxacin 500 mg daily (71%).[113] The lower cure rate with levofloxacin was because of infection with levofloxacin-resistant *Campylobacter* species. Nausea during the 30 minutes after receipt of the first antimicrobial dose was more common in persons given 1 g of azithromycin versus the other regimens (14% vs >6%, respectively).[113]

Rifaximin should not be used in patients with diarrhea complicated by fever and bloody stools, being ineffective against invasive enteropathogens, for example, *Salmonella*, *Shigella*, and *Campylobacter* species.[105]

Case 69-15, Question 4: Based on the symptoms each traveler is experiencing, what drug therapies are available for W.D. and B.D. that can be considered to reduce the duration and severity of their TD?

For travelers with *mild* watery diarrhea without fever or bloody stools (as with W.D.), loperamide can be used, often relieving symptoms in <24 hours.[104] If improvement is not evident within 12 hours, an antimicrobial could be started.[106]

For travelers with moderate-to-severe diarrhea with fever or bloody stools (as with B.D.), antimicrobial therapy is recommended to shorten the duration and severity of the diarrheal illness.[104] Treatment options include fluoroquinolone or azithromycin (**Table 69-3**). Azithromycin is recommended for travelers to areas with a high prevalence of fluoroquinolone-resistant *Campylobacter* species,[104] including Thailand (93%), Nepal (71%), Asia (70%), Latin America (61%), and Africa (31%),[105] or for travelers not responding within 48 hours to a fluoroquinolone.[104] Rifaximin is not effective for TD caused by invasive enteropathogens[16] and is not recommended for B.D.

Table 69-3
Dosing of Agents Commonly Used in *Clostridioides difficile* Infection

Agent	Standard Dosing
Antibacterials	
Vancomycin	125–500 mg orally four times daily for 10 days
Fidaxomicin	200 mg orally twice daily for 10 days
Metronidazole	500 mg orally three times daily for 10–14 days
Adjunctive Agents	
Bezlotoxumab	10 mg/kg IV infusion over 60 minutes, one time

IV, intravenous.

Clinical Practice Guideline by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA): 2021 focused update guidelines on management of *Clostridioides difficile* infection in adults. *Clin Infect Dis*. 2021;73(5):e1029–e1044.

POSTINFECTIOUS COMPLICATIONS OF TRAVELER'S DIARRHEA

Case 69-15, Question 5: Three weeks after returning from their trip, unlike W.D. who is free of intestinal symptoms, B.D. continues to have episodes of loose stools and abdominal discomfort, for which she seeks medical attention. On physical examination, her vital signs are stable and she is afebrile. The physician believes her symptoms are consistent with PI-IBS. What are B.D.'s risk factors for PI-IBS and why is her clinical presentation consistent with this diagnosis? What therapies can be recommended to manage her symptoms?

Clinical Presentation and Risk Factors

Postinfectious complications of TD include reactive arthritis and Guillain–Barré syndrome that are associated with *C. jejuni* infection and PI-IBS, which may occur in 3% to 17% of travelers following a diarrheal episode[16] by invasive pathogens including *Campylobacter*, *Salmonella*, and *Shigella* species.[9] Risk factors for PI-IBS include a severe episode of TD (as with B.D.), the number of episodes, pretravel diarrhea, pretravel adverse life events, and infection with heat-labile toxin-producing ETEC.[16]

Management

Treatment of PI-IBS is aimed at providing symptomatic relief; antimicrobials have not been proven to be beneficial and may be harmful.[114] Diarrheal symptoms can be managed with loperamide; if postprandial fecal urgency is problematic, taking loperamide 30 minutes before meals is recommended. Bloating and abdominal discomfort can be managed with simethicone or antispasmodic agents[75]; chronic abdominal symptoms can be managed with low doses of amitriptyline and selective serotonin reuptake inhibitors.[114] About 50% of patients with PI-IBS recover within 6 years, although recovery is less likely in the setting of persistent depression or anxiety.[114]

Prevention of PI-IBS with chemoprophylaxis of TD has not been proved. A recent randomized, double-blind, placebo-controlled study evaluating prophylactic rifaximin for the prevention of diarrhea in travelers to South and Southeast Asia did not find rifaximin to reduce the occurrence of new-onset irritable bowel syndrome (IBS). The absence of a benefit could be attributed to inadequate power of the study to detect a true difference; more studies are needed to address this issue.[115]

Prophylaxis

Case 69-15, Question 6: On hearing of the travels of W.D. and B.D., friends J.G. and T.M. begin planning a similar vacation to Central America, but they want to prevent the occurrence of any diarrheal illness. Neither friend has any significant medical history. Should prophylaxis be recommended for these travelers? What drug therapies can be recommended for the chemoprophylaxis of TD?

CANDIDATES FOR ANTIMICROBIAL PROPHYLAXIS AND SPECIFIC AGENTS

Antimicrobial prophylaxis for TD is considered when the benefit of prophylaxis outweighs the risks of drug therapy including adverse drug reactions such as photosensitivity with fluoroquinolones, bacterial resistance, and expense.[102],[115] In otherwise healthy persons, TD is typically a self-limiting illness lasting several days, and should it occur, traveler's self-management of TD reduces the time to the last unformed stool to within 24 hours of the onset of illness.[116] For these reasons, routine chemoprophylaxis for TD is not recommended.

Chemoprophylaxis could be considered for travelers at greatest risk for infection or its complications: persons in whom a diarrheal illness could complicate an underlying medical problem (eg, insulin-dependent diabetes mellitus, congestive heart failure, reactive arthritis, inflammatory bowel disease, advanced cancer, or HIV infection); and persons with conditions that increase the risk of

enteric infection (eg, genetic predisposition, gastric disease, or surgery).[102],[107] If offered, chemoprophylaxis should not extend beyond 2 to 3 weeks.[16],[104] Thus, these travelers are not candidates to receive antimicrobial prophylaxis for TD. Instead, at the onset of illness, they should follow their self-treatment plan for TD they received from their pretravel clinic visit.

For travelers who are candidates for chemoprophylaxis of TD, the following options are available.

Antimicrobials

Chemoprophylaxis with a fluoroquinolone (ciprofloxacin 500 mg or levofloxacin 500 mg given daily during travel but not exceeding 2–3 weeks and for 2 days after return) is recommended to reduce the incidence of diarrheal illness.[16],[104] However, the current efficacy of fluoroquinolones should be viewed with caution, given the rising fluoroquinolone resistance in common enteropathogens[115] including ETEC and EAEC in India, and *Campylobacter* species in Asia and Latin America.[105] Azithromycin 250 mg daily is an alternative chemoprophylactic agent and preferred for travel to destinations where *Campylobacter* species is a common cause of TD, for example, South and Southeast Asia.[104]

Rifaximin is not FDA approved for the prophylaxis of TD, but it has been effective for the prevention of TD in students traveling from the United States to Mexico where ETEC is a common enteropathogen.[117] A more recent randomized, double-blind, placebo-controlled study showed only a modest (48% protection) benefit of rifaximin compared to placebo in otherwise healthy travelers to South and Southeast Asia—areas where enteroinvasive pathogens are frequent causes of TD.

Miscellaneous agents

BSS, two tablets (526 mg/dose) four times daily for a maximum of 3 weeks has a protective efficacy of 65% against TD.[118] The problems with BSS because of inconvenient dosing, salicylate content, and unpleasant adverse effects (eg, grayish black fecal and dark tongue

discoloration) should be considered. BSS avoids the acquisition of MDR organisms and changes in the microbiome; therefore, it is recommended for prophylaxis by some organizations.[102]

Probiotics have been studied on the basis of their ability to prevent enteropathogen colonization. The effectiveness of probiotics has not been determined and more studies are needed before these agents can be routinely recommended.[102,105]

ESCHERICHIA COLI O157:H7

Epidemiology

CASE 69-16

QUESTION 1: P.J., a 3-year-old female, is brought to the ED because of "stomach pains" and diarrhea that has progressed from nonbloody to bloody over the past 48 hours. Five days before the onset of diarrhea, the family celebrated her birthday at a fast-food restaurant; P.J.'s parents ate fish sandwiches, and P.J. ate a hamburger. P.J.'s mother noted that the hamburger was not thoroughly cooked because the juices from the hamburger were still pinkish. P.J. has no significant medical history. During the week, she attended a day care center.

On physical examination P.J. is afebrile, with signs of mild-to-moderate dehydration. A stool sample is negative for fecal leukocytes. The physician assesses her illness as bloody diarrhea, possibly caused by Shiga toxin–producing *Escherichia coli* (STEC). The plan is to admit P.J. to the hospital for hydration, observation, and further workup.

What clinical and laboratory findings and epidemiologic history are consistent with the diagnosis of STEC as the cause of P.J.'s illness?

E. coli O157:H7 is a strain of *E. coli* that produces Shiga toxins as one of its mechanisms of causing GI illness. A second virulence factor of STEC strains is their ability to attach to and damage the intestinal mucosa.[119] These *E. coli* bacteria cause a wide spectrum of illness, including asymptomatic carriage, mild and nonbloody

diarrhea, bloody diarrhea (hemorrhagic colitis), HUS, and thrombotic thrombocytopenia purpura.[120]

E. coli O157:H7 should be suspected in the setting of abdominal cramps with nonbloody diarrhea that progresses to bloody diarrhea over 1 to 2 days.[121] Unlike bloody diarrhea associated with *Shigella* or *Campylobacter* species, fever is often absent or of low grade because this pathogen is not invasive.[122] However, patients with severe illness are more likely to have fever.[123]

STEC is most commonly spread by consumption of undercooked beef products that are contaminated with *E. coli* O157:H7, although other modes of acquiring this infection have been reported. The incubation period for this infection is usually 3 to 4 days, which is consistent with P.J.'s recent history of eating undercooked hamburger. In most instances, the illness resolves in 5 to 8 days.[124] Fecal leukocytes may or may not be found in stool samples.[125]

Hemolytic Uremic Syndrome

Case 69-16, Question 2: Forty-eight hours after admission to the hospital, P.J. is pale and has developed several "bruises" on her extremities. The nurse recorded only a minimal output of darkened urine during the past 24 hours. New laboratory test results reveal blood urea nitrogen (BUN), 150 mg/dL; serum creatinine (SCr), 6 mg/dL; serum potassium (K), 6.8 mEq/L; WBC count, 20,000 cells/mm^3; hemoglobin (Hgb), 5 g/dL; platelets, 50,000 cells/mm^3; and urinalysis finding is positive for blood and protein. The stool specimen sent on admission returns a positive result for *E. coli* O157:H7. What complication of *E. coli* O157:H7 infection does P.J. now display?

The new clinical and laboratory findings support the diagnosis of HUS, a well-known complication of STEC infection. HUS is characterized by the triad of thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure with oliguria.[126] On physical examination, P.J.'s "bruises" on her extremities are consistent with thrombocytopenia, which is confirmed by the low platelet count. Her pale appearance is consistent with anemia and is confirmed by the low Hgb. The dark urine is caused by the color

imparted from bilirubin because of red cell lysis (hemolytic anemia). Finally, P.J.'s decreased urine output and increased SCr and BUN concentrations are consistent with renal failure.[127] P.J. has several risk factors for HUS: her age (ie, children age older than 5–15 years, median age 4–8 years), fever, increased peripheral WBC count, and the season of the year (ie, summer).[123],[126],[128–131] Although not present in this case, other possible risk factors for developing HUS are age older than 65 years[125] and treatment with antimotility or antidiarrheal agents,[132] although this has not been universally confirmed.[123],[131] The progression of *E. coli* O157:H7 gastroenteritis to HUS typically becomes apparent about 1 week after the onset of diarrhea.[123],[126],[128] Of children, 3% to 7%[132] may develop HUS, with a mortality rate ranging from 3% to 5%.

In adults, *E. coli* O157:H7 infection progresses to HUS in as many as 27% of patients, with a higher rate in patients age older than 65 years.[123] HUS-related mortality has reached 42% in patients age older than 15 years[123]; elderly patients in nursing homes have a mortality rate of up to 88%.[133]

Treatment

Case 69-16, Question 3: Would P.J. benefit from drug therapy, including antimicrobial, antimotility, or antidiarrheal agents?

Other than supportive measures to manage the complications associated with illness caused by *E. coli* O157:H7, no specific drug therapy for this infection exists.[121] In retrospective and prospective studies, antibiotics have not influenced the severity of illness, the duration of diarrhea or other GI symptoms.[134] When TMP-SMX was started a mean of 7 days after the onset of diarrhea, the duration of *E. coli* O157:H7 excretion was not altered.[135]

The effect of antibiotic administration on the risk of *E. coli* O157:H7 complications (eg, HUS) remains also controversial. A meta-analysis of 17 studies revealed no association between antibiotic administration and development of HUS when all studies

were pooled.[136] This lack of association was similar to an earlier meta-analysis of studies.[137] However, when restricting the newer meta-analysis to higher quality studies with more rigorous definitions, the analysis suggests antibiotic use to increase HUS risks.[136]

Therefore, currently, clinicians do not generally recommend antibiotic treatment for STEC. However, according to active U.S. surveillance reports, nearly two-thirds of patients with this diagnosis receive antimicrobial therapy at some point in their infection, including 29% of patients receiving therapy after confirmed diagnosis.[138] Despite these numbers, P.J. should not receive antibiotic therapy at this time. Clinicians must carefully weigh empiric antibiotic treatment before an organism has been identified.[136]

Antimotility drugs are not recommended for patients with *E. coli* O157:H7 infection because they have been variably associated with an increased risk of progression to HUS,[132] although other studies have failed to find an association.[123],[131] Despite these concerns, recent reports suggest that up to 31% of patients continue to receive antimotility agents for this infection.[138] Although the explanation for the increased risk is unknown, the reduction in bowel motility may decrease the clearance of organisms from the GI tract, thereby increasing the absorption of toxins. Administration of antimotility drugs within the first 3 days of illness has been associated with a longer duration of bloody diarrhea.[139]

Prevention

Case 69-16, Question 4: P.J.'s family members want to know what they could have done to prevent this infection. On discharge from the hospital, is it safe for P.J. to return to her day care center?

STEC is often spread to humans by consumption of contaminated beef products that are not thoroughly cooked.[120] Because thorough cooking kills this organism, meat should be well cooked (ie, juices from meat should be clear, not pink). In addition, this infection can be

acquired by consuming other contaminated foods, including water, unpasteurized milk, apple cider, lettuce, and sprouts.[120],[121]

Finally, because contact with infected persons commonly results in transmission of this infection to others,[132],[133] P.J. should not return to day care until at least 48 hours after her diarrhea has ceased.[134]

CLOSTRIDIOIDES (CLOSTRIDIUM) DIFFICILE INFECTION

Mild-to-Moderate Infection

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 69-17

QUESTION 1: B.W., a 35-year-old female, is admitted to a 10-bed medical ward for the treatment of *Streptococcus pneumoniae* meningitis. On arrival, she is started on ceftriaxone (Rocephin®) 2 g IV every 12 hours and improves over the next few days. On day 7 of antibiotic therapy, she reports feeling warm, with cramping abdominal pain and diarrhea. She begins passing mucoid, greenish, foul-smelling watery stools and has a temperature of 101 °F (38.33 °C). Microscopic examination result of a stool sample is positive for fecal leukocytes. The physician's assessment of B.W.'s clinical and laboratory findings is antibiotic-associated diarrhea (AAD), most likely caused by *C. difficile*.

What is the most likely mechanism for this patient's AAD?

AAD is a common complication of antimicrobial therapy.[140] The mechanisms by which antibiotics cause diarrhea include direct allergic and toxic effects on intestinal mucosa, and alterations of GI motility (eg, erythromycin) and of normal intestinal flora. Changes in the normal bowel flora can lead to changes in carbohydrate or bile acid metabolism by intestinal bacteria or to overgrowth of pathogenic bacteria, either of which may be followed by diarrhea.[140] Bacteria known to be associated with AAD include *C. perfringens*, *S. aureus*,

Klebsiella oxytoca, *Candida* species, and *C. difficile.* CDI is the most clinically relevant microbial cause and the focus of this section.

A spore-forming, gram-positive anaerobic bacillus, *C. difficile* can cause a wide spectrum of syndromes, including asymptomatic carriage, diarrhea of varying severity, colitis with or without formation of pseudomembranes, toxic megacolon, colonic perforation, and death.[140]

The overall incidence of CDI has been decreasing with lower health care–associated infections, but the number of community-associated infections remains stable, now representing nearly half of all CDI infections.[141] The pathogenesis of CDI involves disruption of the normal colonic flora, most commonly by antibiotics. An increasing number of cases in the outpatient setting have been identified without any antibiotic exposure, making additional risk factors difficult to find, although food and pet exposure has been suggested.[141],[142] Recent data suggest that proton-pump inhibitors may be associated with CDI.[143],[144] Alteration of the colonic microflora allows for overgrowth of toxin-producing strains of *C. difficile.* These toxins, primarily toxins A and B, are responsible for causing colonic inflammation and the clinical manifestations of this infection.[140],[141]

A highly pathogenic strain of *C. difficile* has been described in outbreaks in the United States and around the world.[141],[145] This strain, labeled BI/NAP1 (or ribotype 027), generally causes more severe disease. Among its increased virulence factors are an increased production of both toxins A and B and a binary toxin. This ribotype has become endemic in some facilities and appears to cause more severe disease even in nonoutbreak situations, although national rates seem to be decreasing.[141],[146]

Case 69-17, Question 2: Why is B.W.'s history and presentation consistent with AAD caused by *C. difficile*?

B.W.'s major risk factor for acquiring CDI is her receipt of an antibiotic within the last 2 weeks. *C. difficile* is a common cause of nosocomial diarrhea. The clinical and laboratory findings consistent

with CDI include nonbloody, mucoid, greenish, foul-smelling watery stools and crampy abdominal pain. Patients usually present with low-grade fevers, but temperature may be >104 °F (40 °C).[147] Peripheral leukocytosis is common with CDI, sometimes with WBC >30,000 cells/mm^3.[147],[148] Fecal leukocytes are variably present in CDI and are not clinically useful for diagnosis.[149]

The onset of symptoms of CDI varies widely from a few days after the start of antibiotic therapy to 8 weeks after the agent is discontinued.[147] Other risk factors for acquiring CDI are admission to a hospital in which *C. difficile* is endemic, including asymptomatic carriage, or in which there is an ongoing outbreak of CDI.

Case 69-17, Question 3: How can B.W.'s diagnosis of CDI be confirmed?

Finding toxins in unformed stool of symptomatic patients is the gold standard for diagnosis. A two-step diagnostic method is currently recommended. The two-step test first looks for the presence of glutamate dehydrogenase (GDH) antigen as a quick and inexpensive screening test. GDH is produced by all *C. difficile* strains, so positive GDH tests are then followed by toxin-detecting nucleic acid amplification testing (NAAT) or enzyme-linked immunoassay (EIA).[150] Samples with negative results for GDH are considered negative and not tested further. Culture, although helpful, is complicated by the fact that of the *C. difficile* strains isolated from various populations, 5% to 25% do not produce toxins (nontoxigenic) and do not cause colitis or diarrhea.[147] Routine testing for specific *C. difficile* strains such as ribotype 027 is not typically available in most settings.[150]

Colonoscopy with biopsy may be used to diagnose *C. difficile* colitis through its characteristic colonic changes, which are raised, yellowish nodules or plaque-like pseudomembranes, often with skip areas of normal mucosa.[147]

Case 69-17, Question 4: How can B.W.'s CDI be differentiated from enigmatic AAD?

Only 10% to 20% of cases of AAD have positive findings for toxigenic *C. difficile*; the remaining cases have an unknown cause and are referred to as simple, benign, or "nuisance" diarrhea.[140] Benign diarrhea is a self-limited illness that resolves with nonspecific supportive measures and discontinuation of antibiotics. These clinical entities can be differentiated from one another by several objective measures. In hospitalized patients, watery diarrhea, low functional capacity, acid suppression, low albumin, and a WBC >13,000 cells/mm^3 were significant predictors of CDI.[151] Other clinical features that suggest CDI rather than enigmatic diarrhea are constitutional symptoms, lack of an antibiotic dose relationship to the illness, and hospital-wide epidemics of diarrhea.[152]

TREATMENT

Case 69-17, Question 5: B.W.'s stool sample is positive for both GDH and *C. difficile* toxin. What is the general plan to treat B.W.'s CDI?

After replacement of fluids and electrolytes, there are several steps to most effectively manage B.W.'s CDI. The first is to discontinue the offending drug (if possible), which in B.W.'s case is probably the antibiotic ceftriaxone. Although some data suggest that withdrawal of the precipitating antibiotic and supportive care may be sufficient for mild disease, all available guidelines suggest specific antimicrobial treatment.[153]

Because B.W. is being treated for bacterial meningitis, a life-threatening infection, discontinuing antibiotics is not an option. A second option is to change her antimicrobial therapy to an agent less likely to cause CDI. B.W. is taking a cephalosporin, which, as with ampicillin, amoxicillin, clindamycin, and the fluoroquinolones, is frequently implicated as a cause of *C. difficile* diarrhea. In contrast, antibiotics, such as TMP-SMX, and aminoglycosides, are less commonly associated with CDI.[154–156] None of these antimicrobials, however, is a suitable alternative for treating *S. pneumoniae* meningitis.

B.W. should also receive therapy directed against *C. difficile* while continuing to take ceftriaxone for the treatment of her bacterial meningitis.

Specific *Clostridioides difficile*–directed antimicrobials

Case 69-17, Question 6: What antibiotic should be selected to treat B.W.'s CDI?

The oral agents currently used to treat CDI are vancomycin, fidaxomicin, and metronidazole (if none of the previous agents is available) (Table 69-3). The differentiation between these three agents is complex and evolving, but it is guided in part by severity of illness and concern for recurrence.[157–161] The most optimal definition of severe disease is not well established, but general markers of instability of vital signs with high white counts and changes in albumin and SCr are suggested[150] (**Table 69-4**). In patients categorized as having mild-to-moderate disease severity, vancomycin or fidaxomicin are generally recommended as the preferred initial agents, a major change from earlier guidance that suggested metronidazole as the first-line agent.[150,158] Two major trials comparing metronidazole and vancomycin[162,163] in contemporary *C. difficile* settings reported superiority of vancomycin to metronidazole in mild/moderate disease, prompting the relegation of metronidazole as a second-line agent. This hierarchy of efficacy for vancomycin and fidaxomicin over metronidazole was confirmed in a Cochrane review of 22 studies on *C. difficile* treatment.[153] Recent reports have shown increases in *C. difficile* resistance to both metronidazole and vancomycin, but the clinical significance in treatment selection is unknown.[164] Antibiotic sensitivities, therefore, are not routinely performed on *C. difficile*.

Table 69-4
***Clostridioides difficile* Infection Severity of Disease**

	Published Guidelines

Severity	*ESCMID 2014*	*SHEA/ISDA 2017*
Mild-to-moderate	Diarrhea plus signs and symptoms that do not meet severe or complicated criteria	White blood count ≤15,000 cells/mL *and* Serum creatinine <1.5 mg/dL
Severe	CDI with (one or more specific signs and symptoms of) severe colitis or a complicated course of disease, with significant systemic toxin effects and shock, resulting in need for ICU admission, colectomy or death; or one or more of the following: 1. Marked leucocytosis (leucocyte count >15 × 10^9/L) 2. Decreased blood albumin (<30 g/L) 3. Rise in serum creatinine level (≥133 μM or ≥1.5 times the premorbid level)	White blood count ≥15,000 cells/mL *or* Serum creatinine >1.5 mg/dL
Fulminant	N/A	Hypotension or shock, ileus, megacolon

ICU, intensive care unit; N/A, not applicable.

Sources: McDonald LC, Gerding DN, Johnson S, et al. Clinical practice guidelines for *Clostridium difficile* infection in adults and children: 2017 update by the Infectious Diseases Society of America (IDSA) and Society for Healthcare Epidemiology of America (SHEA). *Clin Infect Dis*. 2018;66(7):987–994; Debast SB, Bauer MP, Kuijper EJ, European Society of Clinical Microbiology and Infectious Diseases. European Society of Clinical Microbiology (ESCMID) and Infectious Diseases: update of the treatment guidance document for *Clostridium difficile* infection. *Clin Microbiol Infect*. 2014;20 Suppl 2:1–26.

Oral vancomycin produces fecal concentrations that are several 100 times the concentration needed to inhibit toxin-producing strains of *C. difficile.*[161] A 10-day course of oral vancomycin (125 PO four times daily) is recommended for the treatment of mild/moderate CDI.[150] IV vancomycin is not effective for treatment. Although oral

vancomycin is not well absorbed, measurable serum concentrations have been found in patients with both normal and compromised renal function, although higher and longer dose regimens, severe infection, and renal dysfunction were more associated with serum concentrations.[165]

Fidaxomicin is the newest antimicrobial indicated for the treatment of CDI.[166],[167] Fidaxomicin is a macrocyclic antibiotic active against *C. difficile* that is poorly absorbed and achieves high colonic concentrations.[168] It has limited antimicrobial spectrum and largely preserves colonic flora. In the clinical trials, patient outcomes on initial infection were similar when compared with vancomycin.[167] Although at a significantly higher cost of therapy, one potential advantage for fidaxomicin is in recurrence rates, which were found to be significantly lower with fidaxomicin compared to vancomycin (15.4% vs 25.3%, P = .005). Some clinicians and the most recent IDSA guidelines are now suggesting this advantage is large enough to prefer fidaxomicin over vancomycin in many patient groups.[169],[170] A recent meta-analysis suggests fidaxomicin may have better outcomes than does vancomycin in all but severe infection.[169] Although recurrence is a concern in CDI treatment, it is not yet clear if it is possible to identify patients for whom the higher cost would provide an additional benefit from this effect.

Metronidazole is well absorbed after oral administration and is excreted through the biliary tract before reaching the colon. Because metronidazole is a carcinogen and, in some animal species, a mutagen, it should be used in pregnancy only if clearly needed. Similarly, metronidazole's safety in children has not been proved, and many prefer not to use it in this population if other options exist.[154]

Because B.W. is not critically ill, vancomycin (125 mg PO four times daily) for 10 days is recommended as first-line treatment.[150] Oral fidaxomicin is generally considered equally efficacious in mild-to-moderate disease, with some suggestions of superiority to vancomycin in pooled analyses.[150],[170],[171] Oral vancomycin capsules and a prepared oral solution are expensive but less than fidaxomicin and more than a course of oral metronidazole. Some of this cost

differential can be offset using the IV vancomycin preparation to prepare an oral solution that can be flavored and prepared as directed in the package insert. Once therapy directed against *C. difficile* is initiated, diarrhea or cramping should subside within 2 to 4 days.

ALTERNATIVE THERAPIES

Probiotics

Using probiotics introduces probiotic microorganisms into the normal flora to counteract disturbances and reduce the colonization with pathogenic species.[172] Orally administered *Lactobacillus* species and the yeast *S. boulardii* have been used to treat CDI, but no good data support the use of probiotics alone. Adjunctive use has been suggested to prevent CDI and its recurrences. A hospital trial looking at prevention of all AAD with *Lactobacillus* reported positive results for the prevention of CDI.[173] A Cochrane review of 31 studies looking at probiotics for the prevention of CDI found a positive benefit, particularly in patients with a higher baseline risk of CDI.[174] Although positive results have been suggested, there is caution to the widespread use of probiotics, with reports of isolated adverse effects, including fungemia, with ingestion of viable *S. boulardii* being reported.[158],[175]

Antidiarrheals

CASE 69-17, QUESTION 7: Should B.W. be given any antidiarrheal agent to relieve her symptoms?

Opiates and other antiperistaltic agents should be avoided in patients with CDI. Although these types of drugs may relieve diarrheal symptoms, they may also delay toxin removal from the GI tract. Evidence supporting these negative effects is minimal because data are scarce,[11] but caution would suggest avoiding any antimotility agent in B.W.

Case 69-17, Question 8: Following resolution of B.W.'s CDI, is it necessary to send a follow-up stool sample to determine whether it is negative for *C. difficile* toxin?

After resolution of diarrhea, obtaining a follow-up stool sample to determine whether it is negative for *C. difficile* toxin is not recommended as part of routine practice because many test results may remain positive for an extended duration and most patients with continued positive test results will not develop a recurrence of their diarrhea.[150] In addition, up to 3% of healthy adults carry small numbers of *C. difficile* in their feces, whereas colonization rates are much higher (31%–37%) in hospitalized patients and infants under 1 month.[176],[177]

Transmission

CASE 69-18

Question 1: Over the next few days, five patients on the ward with B.W. are found to have *C. difficile* toxin in their stools. Three patients have diarrhea and the other two are asymptomatic.

What is the role of hospital-wide stewardship interventions in controlling this outbreak?

Controlling overall antibiotic use in the hospital is considered a very useful strategy. Antimicrobial stewardship is increasingly seen as a major control mechanism for CDI.[150] Restricting the use of agents such as clindamycin and fluoroquinolones can be an effective component in efforts to control nosocomial outbreaks of CDI, especially with the emergence of the BI/NAP1 strain.[178],[179] A meta-analysis of antibiotic stewardship impacts on *C. difficile* revealed a 32% reduction in incidence when implemented.[180]

Thorough cleaning and disinfecting of the hospital environment is important to limit spread. In addition, hand hygiene remains of particular importance. It should be noted that, in addition to alcohol-based hand sanitizers, soap and water hand hygiene is

recommended because alcohol-based hand sanitizers do not reliably kill *C. difficile* spores that can be spread from patient to patient.[150]

Finally, the overuse of acid-suppressive therapy in the hospital setting, particularly proton-pump inhibitors, has been linked to increases in CDI.[180] Efforts to control the use of these drugs have been increasingly recommended.[181]

Case 69-18, Question 2: What effect will the current CDI outbreak have on the outcomes of the infected patients and on health care costs?

In a prospective study, hospitalized patients who developed CDI had a 3.6-day increase in length of stay.[182] A large retrospective cohort study in the Veterans Affairs Administration reported a 2.3-day increase in hospitalization, with an increase of 4.4 days with severe disease.[183] A review of available economic data suggests additional hospital costs of $8900 to $30,000 for each case of CDI.[184] In addition, CDI has been shown to decrease the likelihood that hospitalized patients be discharged to home, with a significant increase in hospice or long-term care transfers.[185] The current outbreak on the hospital ward is likely to increase both hospital costs and individual lengths of stay and may impact patient discharge locations.

Severe *Clostridioides difficile* Infection

CASE 69-19

Question 1: H.T. is a 76-year-old who has also developed CDI on the ward. His temperature is 102 °F (38.89 °C), WBC is 22,000 cells/mL, and he is hypotensive. He currently has severe abdominal pain, a computed tomography (CT) scan result is showing pseudomembranes, and he is being evaluated for possible surgical intervention.

What treatment is recommended for H.T. who is critically ill from a CDI? What criteria should be used to characterize patients as “critically ill”?

Up to 57% of patients with antibiotic-associated pseudomembranous colitis who require surgical intervention (colectomy) die.[186] Although the precise definition of "critically ill" is not clear, it has variably included patients with pseudomembranes, age older than 60, serum albumin >2.5 mg/dL, fever >100.94 °F (38.3 °C), severe abdominal pain, and marked leukocytosis (>15,000–20,000 cells/mL).[147],[162] Guidelines from the Society for Healthcare Epidemiology of America and the IDSA have suggested the definition of severity as the presence of either of the following two parameters: WBC count ≥15,000 cells/mL or SCr >1.5 mg/dL. An additional definition of "fulminant" disease has been suggested for patients such as H.T. who have hypotension, shock, ileus, or megacolon[150] (see Table 69-4). The recommended therapy for H.T. would be a combination of high-dose vancomycin (500 mg) PO four times daily and metronidazole 500 mg IV every 8 hours.[150] This combination therapy was shown to reduce mortality from 36.4% to 15.9% when compared with monotherapy in a small observational study.[187] The combination of high-dose therapies is theorized to overcome the difficulties for either medication to get to the site of action in the colon.

NONORAL TREATMENT

CASE 69-19, QUESTION 2: Three days after oral vancomycin and IV metronidazole is initiated, H.T. develops an ileus and cannot take anything by mouth. What therapeutic options are available to treat H.T.'s pseudomembranous colitis?

Adequate antibiotic levels in the colon are necessary to treat *C. difficile*–associated pseudomembranous colitis. If the oral route is not feasible (eg, patients with an ileus or bowel obstruction), the clinician must choose an agent that is either secreted or excreted into the GI tract in its active form. IV vancomycin is not a desirable agent in this situation because it is not secreted into the GI tract. In contrast, IV metronidazole is eliminated by both renal and hepatic routes, and bactericidal concentrations are achieved in both serum and bile.[188]

The literature contains few reports of successful attempts to treat CDI or pseudomembranous colitis with IV metronidazole (500 mg every 6–8 hours) alone.[189–191] Likewise, unsuccessful attempts to treat CDI with IV metronidazole have been reported.[189,192] The clinical response of CDI to PO vancomycin in a patient who did not survive was difficult to ascertain.[161]

In adults, enteral vancomycin 500 mg four times daily can be given through a nasogastric tube, or an ileostomy or colostomy (if present). Several reports of successful outcomes using intracolonic vancomycin (as an adjunct to oral/enteral vancomycin or to IV metronidazole) in patients with CDI have been documented, and this approach is currently recommended.[150,170] Rectal doses of vancomycin have varied from 500 mg every 4 to 8 hours to 1000 mg/L every 8 hours.[193] Rectal vancomycin administration volumes of 500 mL are suggested to better ensure delivery to the transverse and distal colon.[150] Saline can be used as a carrier, but electrolytes should be monitored because absorption can occur. Lactated Ringer solution may be preferred if hyperchloremia is present.[7]

Because patients with CDI are at risk for colonic perforation, some clinicians suggest that enteral vancomycin be administered cautiously.

Recurrence

CASE 69-20

Question 1: P.V. is a 57-year-old male who acquired CDI on the same ward as the other infected patients. P.V. was treated with vancomycin 125 mg PO four times daily for 10 days while in the hospital. Two weeks after discharge from the hospital, P.V. once again developed abdominal pain and diarrhea. His clinic physician assumed these symptoms could not be related to a recurrence of his CDI because he had responded so well to vancomycin.

What is the likelihood that CDI has recurred?

Regardless of the antibiotic regimen prescribed for CDI, symptomatic recurrence occurs in 5% to 30% of patients who

respond to their initial treatment regimen.[150],[155] Recurrences occur 2 weeks to 2 months (median of 7 days) after treatment has been discontinued.[194] In most instances, recurrences are caused by germination of dormant spores that are intrinsically resistant to antibiotics. Reinfection with *C. difficile* from external sources, however, may account for up to half of all second episodes.[195] In rare instances, either vancomycin[196] or metronidazole[197] may have caused CDI.

Risk factors for recurrent CDI include increasing age (≥65 years), immune dysfunction, renal insufficiency, use of proton-pump inhibitors, continued use of antimicrobials during CDI treatment, glucocorticoid use, and certain *C. difficile* strains.[198–200] Further refinement of these risk factors may allow for the prediction of recurrences and guide tailored treatment options or the addition of other therapeutics in high-risk patients.

Data suggest that patients with a poor immune response to *C. difficile* toxin A are more likely to have a recurrence of CDI.[200] It is not clinically helpful in the case of P.V. because no standard tests are currently available for this immune response. The influence of the immune system, however, has led to the usage of IV immune globulin in refractory or severe cases of CDI.[201],[202] However, utility of the usage of immune globulins is still debated. Immune globulins would not be considered the next line of therapy for P.V.

Case 69-20, Question 2: How should P.V.'s CDI recurrence be treated?

Most infections resulting from recurrence are not related to bacterial resistance, and they may respond to retreatment with the same antibiotic used for initial treatment of the CDI.[155],[203] However, current recommendations suggest switching agents and considering alternate dosing strategies.[150],[170] Thus, an appropriate approach for P.V. is to administer a 10-day course of fidaxomicin 200 mg PO twice daily.

For patients with multiple recurrences of CDI, the optimal management plan is unresolved. Different approaches have been

tried, including (a) high-dose vancomycin (2000 mg/day PO)[204]; (b) a 4- to 6-week course with vancomycin, after which the dose is tapered over a 1- to 2-month period[204],[205]; (c) exchange resins[206],[207] with or without antibacterials; (d) “pulse” dosing of vancomycin every 2 to 3 days[204]; or a combination of vancomycin and rifampin (600 mg PO twice daily).[208] Tapered and pulse therapy with vancomycin was shown to be most effective in a clinical trial comparing multiple strategies and is now recommended.[170],[204]

When combined with standard antibiotic therapy, a clinical trial with the probiotic *S. boulardii* for cases of relapsing CDI noted a 65% response rate versus a 36% response rate for combination therapy with placebo.[209] The recurrence rate was reduced to 17% when *S. boulardii* was combined with high-dose vancomycin.[210]

Following treatment with vancomycin, a “chaser” course of rifaximin, a poorly absorbed rifamycin derivative, was successful in separate case series for patients with multiple recurrences.[211],[212] The most recent guidelines suggest rifaximin 400 mg PO three times daily for 20 days after a 10-day course of vancomycin 125 mg PO four times daily as an alternative for second or subsequent CDI recurrence.[170] Concern must be raised that the single failure occurred in concert with emerging rifaximin resistance.[211]

Because of its more minimal impact on fecal flora, fidaxomicin is recommended for recurrent infections, although there is less evidence for its use in recurrence compared to other recommended agents.[150],[170] Despite its much higher cost, fidaxomicin’s inherent advantage in limiting recurrence with initial treatment and treatment of first recurrences may lie in overall cost savings.[213],[214] A recent trial in older adults suggested that extended pulsed use of fidaxomicin 200 mg twice daily for 5 days followed by every other day dosing from days 7 to 25 led to low recurrence rates of 6% at 90 days versus 19% with conventional vancomycin dosing.[215]

Bezlotoxumab is a newly approved monoclonal antibody infusion directed against *C. difficile* toxin B. Bezlotoxumab does not have direct antibacterial activity against *C. difficile*, but it has been shown to reduce recurrence rates when combined with antimicrobial therapy in high-risk patients. In published studies, bezlotoxumab 10

mg/kg as a single infusion during antimicrobial treatment for *C. difficile* resulted in an absolute 10% reduction in recurrence rates of disease.[216] Further evaluation was completed for patients stratified by number of risk factors for recurrence, for example, age 65 years or older, history of CDI in the previous 6 months, compromised immunity, severe CDI, and isolation of a strain associated with poor outcomes (ribotypes 027, 078, or 244).[200] In this analysis, having three or more risk factors for recurrence showed the greatest benefit from bezlotoxumab with a 24.8% absolute reduction in recurrence, compared to a 14.2% reduction with one or two risk factors. Patients without known risk factors for recurrence did not gain a significant benefit from bezlotoxumab treatment. The cost of this therapy is significant (~$3800), and bezlotoxumab's exact place in therapy is currently under debate.[217] The new IDSA guidelines suggest its co-use to standard CDI treatment in patients with a recurrent CDI episode within the past 6 months as risk reduction of a subsequent CDI recurrence after initial clinical cure, whereas the American College of Gastroenterology (ACG) guidelines suggest its use as CDI prevention only in patients at high risk for recurrence.[170],[218] Further, owing to the potential for exacerbating heart failure, bezlotoxumab should be given with caution in patients with this disease.

Finally, fecal microbiota transplant (FMT) therapy has been more widely investigated in second and third recurrences and has shown significant promise.[219] Healthy fecal donors, often family members, are the usual source of fecal microbiota, although frozen "banks" of FMT samples have been increasing along with newly lyophilized versions.[220],[221] Administration of FMT can be provided through nasogastric or nasojejunal tubes, colonoscopy, or colonic enemas. Although published data overall remain small, a systematic review of the literature supports the efficacy (85% cure rates) and limited adverse effects of this therapy.[219] Long-term follow-up from 137 patients treated with FMT found an 82% durable response rate without recurrence.[222] A single cost-effectiveness model, using literature-based data, found FMT to be more cost-effective compared to treatment of recurrences with vancomycin.[223] The current CDI

guidelines recommend FMT after at least the second CDI recurrence to prevent further recurrent CDI.[218]

70

Intra-Abdominal Infections

Christie M. Bertram and Sheila K. Wang

CORE PRINCIPLES		CHAPTER CASES
1	Acute cholecystitis is the acute inflammation of the gallbladder, presenting with fever, prolonged abdominal pain, and positive Murphy's sign of the right upper quadrant followed by nausea and vomiting. Acute cholangitis is an acute inflammation of the common bile duct with the accompanying classic Charcot triad: fever, jaundice, and right upper quadrant pain.	**Case 70-1 (Question 1)**
2	Enterobacterales (aerobic enteric gram-negative rods) are most commonly associated with biliary tract infections, which include pathogens such as *Escherichia coli (E. coli), Klebsiella* species, and *Enterobacter* species. The	**Case 70-1 (Question 2)**

	choice of antibacterial agents is largely empiric covering these common pathogens.	
3	Empiric therapy for severe biliary tract infections may include combination therapy with ciprofloxacin, levofloxacin, or cefepime plus metronidazole or monotherapy with piperacillin/tazobactam or an antipseudomonal carbapenem (imipenem/cilastatin or meropenem) if multidrug-resistant gram-negative rods are suspected.	**Case 70-1 (Question 3)**
4	Adequate serum concentrations of recommended antibacterial agents coupled with targeted source control (ie. biliary drainage) are most important when managing biliary tract infections. Duration of therapy for intra-abdominal infections typically ranges from 4 to 7 days. Clinical response and source control influence duration of therapy.	**Case 70-1 (Question 4)**
5	Spontaneous bacterial peritonitis (SBP) is largely a monomicrobial infection commonly caused by Enterobacterales.	**Case 70-2 (Question 1)**
6	Empiric therapy for SBP may include a third-generation cephalosporin such as ceftriaxone or cefotaxime or parenteral fluoroquinolone with activity versus *Streptococcus pneumoniae*. Length of therapy depends on the reduction in polymorphonuclear leukocyte counts	**Case 70-2 (Question 2)**

	(<250 cells/μL) in peritoneal fluid, generally occurring in ≤5 days.	
7	Due to the selection of resistant bacteria, long-term prophylaxis to prevent SBP is recommended for those at high risk for developing SBP (eg. previous episodes of SBP, cirrhosis with GI bleed, low ascitic protein of < 1.0 g/dL).	**Case 70-2 (Question 3)**
8	Empiric therapy for Continuous Ambulatory Peritoneal Dialysis (CAPD)-associated peritonitis should target the most common causative organisms which included gram-positive bacteria such as *Staphylococcus* and *Streptococcus* species, followed by gram-negative Enterobacterales, with *E.coli* being the most common. The intraperitoneal (IP) route is preferred except in the setting of systemic sepsis.	**Case 70-3 (Question 1)**
9	In general, fluconazole is the agent of choice for *Candida albican*-associated CAPD peritonitis with temporary catheter removal.	**Case 70-3 (Question 2)**
10	Signs and symptoms of secondary peritonitis may include moderate to severe abdominal pain with anorexia, nausea, vomiting, fevers with or without chills, tachycardia, faint or absent bowel sounds, abdominal distention, and an elevated WBC count.	**Case 70-4 (Question 1)**
11	The most likely pathogens for	**Case 70-4 (Question**

	secondary peritonitis are facultative gram-negative organisms such as *E. coli, Proteus* species, *Klebsiella* species, or *Enterobacter* species or an anaerobe such as *Bacteroides fragilis*.	**2)**
12	Therapy for secondary peritonitis should include antimicrobial coverage directed at gram-negative bacteria and anaerobes. Therapy may include (a) certain extended-spectrum β-lactams or β-lactamase inhibitor combinations, (b) carbapenems, or (c) a fluoroquinolone with metronidazole stratified according to severity of infection (ie, mild-to-moderate risk vs high risk).	**Case 70-4 (Question 3)**
13	In general, coverage of *Enterococcus* species is warranted if it is present in blood cultures or is the sole organism on culture.	**Case 70-5 (Question 1)**
14	*Candida* species should be treated when isolated surgically or directly from an intra-abdominal collection in patients with severe community-acquired or healthcare-associated infections.	**Case 70-5 (Question 2)**
15	Definitive culture and susceptibility reports for anaerobes may take days to weeks to finalize; therefore, empiric antibiotic regimens should cover for anaerobes when suspected.	**Case 70-5 (Question 3)**
16	Optimal antimicrobial therapy for the treatment of intra-abdominal abscesses should penetrate the abscess in	**Case 70-6 (Question 1)**

	adequate concentrations and have an adequate spectrum of activity.	
17	Antimicrobial therapy targeting both aerobic and anaerobic pathogens should be used in the treatment of infections due to penetrating trauma.	**Case 70-7 (Question 1)**
18	Acute penetrating abdominal trauma requires a short course (<24 hours) of antimicrobial therapy. Delay in therapy or development of infection necessitates a 5- to 7-day course of therapy.	**Case 70-7 (Question 2)**
19	Antimicrobial therapy for appendicitis follows the recommendations for community-acquired intra-abdominal infections.	**Case 70-8 (Question 1)**

INTRODUCTION

Despite the introduction of new antimicrobial agents and improvements in diagnostic and surgical techniques, the treatment of intra-abdominal infections remains a therapeutic challenge. However, advances in radiographic and interventional techniques with timely source control, improved fluid and nutritional management, and the selection of appropriate antimicrobial agents have decreased mortality in intra-abdominal infections.[1]

Intra-abdominal infections are those contained within the peritoneal cavity, which extends from the undersurface of the diaphragm to the floor of the pelvis or the retroperitoneal space. Intra-abdominal infections can present as a localized infection (eg, appendicitis), a diffuse inflammation throughout the peritoneum (eg, peritonitis), or as abscesses, which can form anywhere within the

abdomen, between bowel loops, or in solid organs such as the liver, biliary tract, spleen, pancreas, or female pelvic organs. Antibiotic selection will depend on the type of intra-abdominal infection. Most intra-abdominal infections are community acquired (80%), which can be either mild-to-moderate risk or high risk depending on the severity of the infection, comorbidities, and involvement of drug-resistant pathogens. Health care–associated intra-abdominal infections generally involve more nosocomial bacteria and fungi with a greater risk factor for multidrug resistance. Intra-abdominal infections can also be categorized as uncomplicated and complicated. Uncomplicated intra-abdominal infections involve a single organ without spread to the peritoneum, whereas complicated intra-abdominal infections (cIAIs) extend beyond the hollow viscus of origin into the peritoneal space (eg, abscess or peritonitis).[2]

Empiric antimicrobial therapy should be initiated as soon as an intra-abdominal infection is suspected. In addition to the type of infection, therapy should be selected on the basis of the suspected pathogens; however, antimicrobial therapy alone may be insufficient, especially in the setting of diffuse peritonitis. *Source control* is a term used to involve all physical measures needed to eradicate an infection, such as debridement of necrotic tissue or drainage of an abscess or fluid collection. If adequate source control is delayed, bacteremia, multiple organ failure, and mortality are more likely to occur.[3]

Normal Gastrointestinal Flora

The stomach of fasting individuals contains very few bacteria as a result of gastric motility and the bactericidal activity of normal acidic gastric fluid.[1] The bacterial population of the stomach can be altered by drugs or diseases that increase gastric pH or decrease gastric motility. Not surprisingly, patients with bleeding or obstructing duodenal ulcers, gastric ulcers, gastric carcinomas, or those receiving proton-pump inhibitors or histamine-2 (H_2) receptor

antagonists have an increased number of oral bacteria colonizing the stomach.

The upper small intestine (duodenum and jejunum) usually contains relatively few bacteria and harbors mainly oral flora. The lower small intestine serves as a transitional zone between the sparsely populated stomach and the abundant microbial flora of the colon.[2,4]

In the ileum, facultative gram-negative and gram-positive species, as well as obligate anaerobes, are encountered. As the distal ileum is approached, the quantity and variety of bacteria increase. Substantial numbers of anaerobic bacteria are present, including *Bacteroides* species, as well as *Escherichia coli* (*E.coli*) and *Enterococcus* species.[1,2]

In the large bowel, anaerobic bacteria, particularly *Bacteroides* species, predominate. In the distal colon, bacterial counts average 10^{10} colony-forming unit (CFU)/mL of feces, with anaerobes outnumbering other organisms by a ratio of 1000 to 10,000:1.[2] Among the facultative aerobes, *E. coli* is the most frequently isolated species.[1,2] Given these differences in regional microflora populations, it is not surprising that trauma to the colon carries a much higher risk of intra-abdominal infection in comparison with the stomach or jejunum[5] (**Fig. 70-1; Table 70-1**).

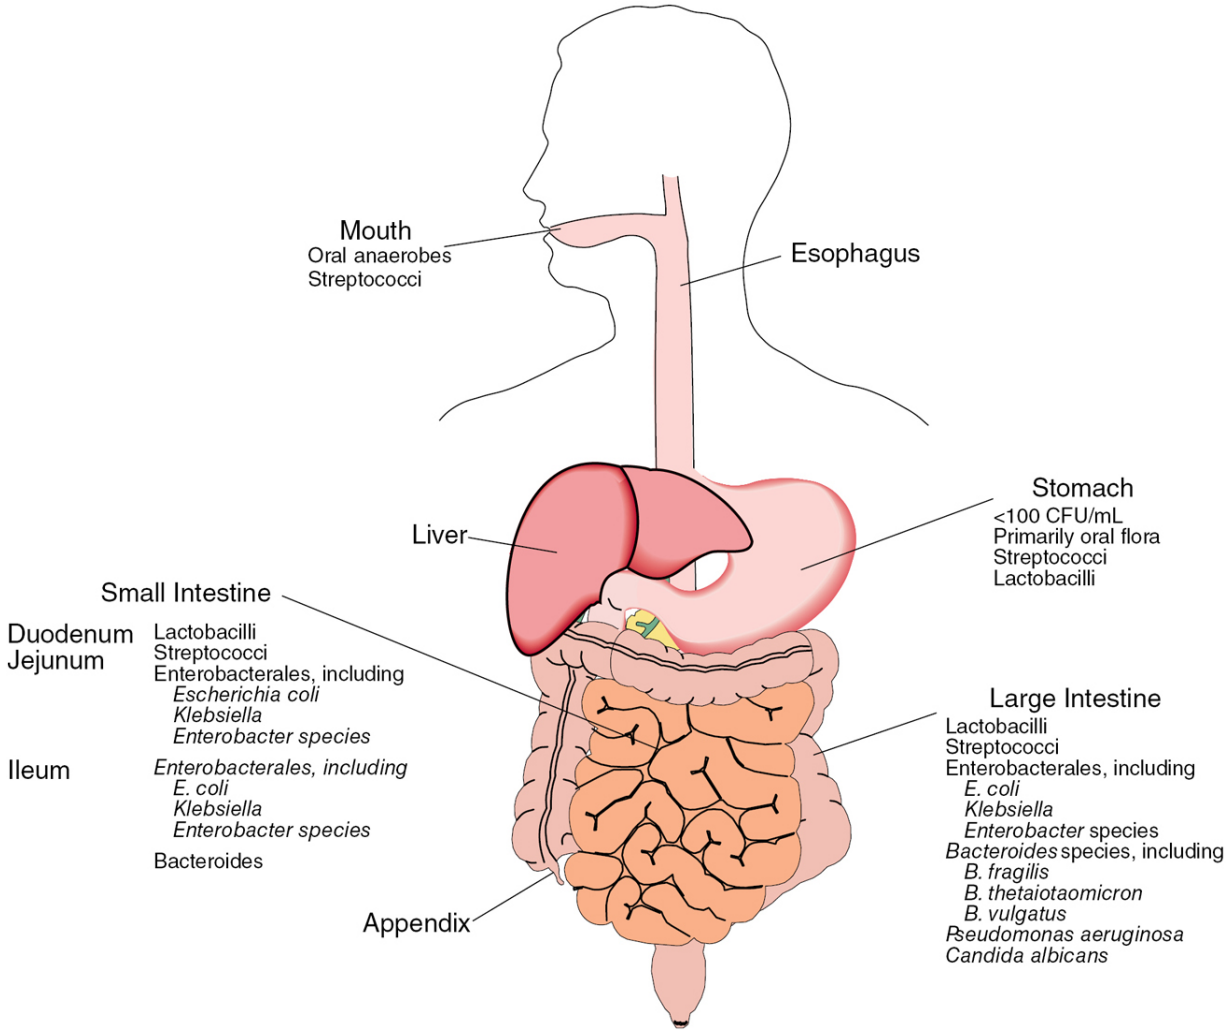

Figure 70-1 Microflora of the gastrointestinal tract.

Table 70-1
Common Pathogens in Intra-Abdominal Infection

Disease	Common Pathogens	Comments
Cholecystitis, cholangitis	*Escherichia coli*, *Klebsiella pneumoniae*, *Enterococcus*, and anaerobes	*Enterococcus* species and anaerobes are less frequently isolated, but they have been associated with nosocomial infections and chronic surgical infections, particularly in patients receiving broad-spectrum antimicrobials.
Primary peritonitis	*E. coli*, *K. pneumoniae*, *Streptococcus*	Also known as spontaneous bacterial peritonitis presented in patients with

	pneumoniae, occasional anaerobes	cirrhosis. Often monomicrobial. Anaerobes less likely than aerobes.
Secondary peritonitis	*E. coli*, *Bacteroides fragilis*, *Enterococcus*, and anaerobes	Generally polymicrobial with both aerobic and anaerobic pathogens. *Enterococcus* species should be considered in the setting of health care–associated infections.
Chronic ambulatory peritoneal dialysis	*Staphylococcus epidermidis*, *S. aureus*, diphtheroids, gram-negative rods	Dwell time of exchange with intraperitoneal antibiotics must be a minimum of 6 hours.

As noted earlier, resistant flora are more common in health care–associated infections, including *Pseudomonas aeruginosa*, *Acinetobacter* species, extended-spectrum β-lactamase (ESBL)-producing organisms, carbapenemase-producing *E. coli* and *Klebsiella* species, methicillin-resistant *Staphylococcus aureus* (MRSA), enterococci, and *Candida* species.[6–10]

INFECTIONS OF THE BILIARY TRACT

Cholecystitis and Cholangitis

Cholecystitis and cholangitis originate as inflammatory conditions, usually as a result of obstruction in the gallbladder or common bile duct, respectively. The obstruction is typically caused by the presence of stones. The biliary tract is sterile under normal conditions, and the flow of bile, along with its bacteriostatic properties, functions to maintain the sterility. Infection typically occurs as a secondary event to obstruction.[4,5] The location, degree, and length of time of the obstruction can influence the development of pancreatitis, cholangitis, or hepatic abscesses.[11]

Acute cholecystitis is the acute inflammation of the gallbladder. The presence of gallstones in >90% of cases prevents the outflow of gallbladder drainage by obstructing the neck of the gallbladder, the Hartmann pouch, or the cystic duct.[4] The obstruction causes an increase in intraluminal pressure, gallbladder distension, and edema, which triggers an acute inflammatory response. The potential consequences of this obstruction and inflammation include infection, ischemia, perforation, and necrosis.[4,12] The reduction in gallbladder outflow leads to biliary stasis, which provides an ideal environment for bacterial proliferation and subsequent infection (see **Fig. 70-2**).

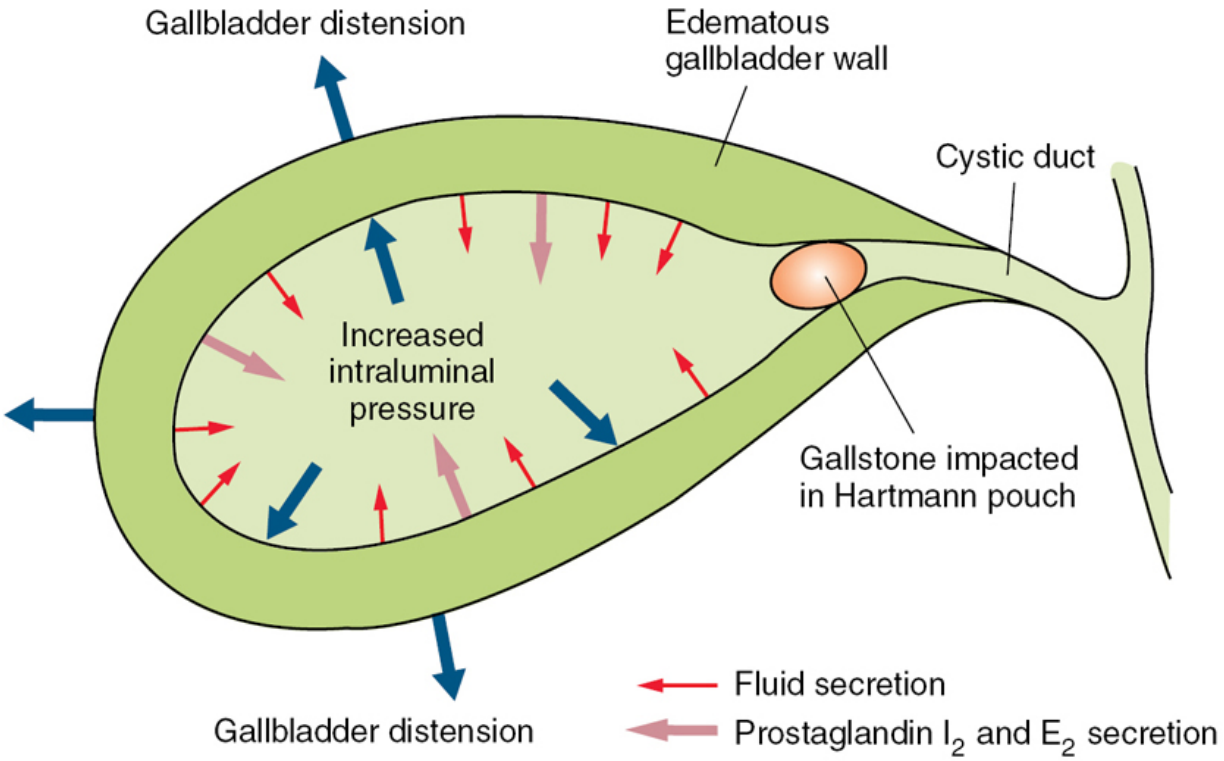

Figure 70-2 Pathogenesis of acute cholecystitis.

Acute cholangitis is an acute inflammation of the common bile duct. The most common cause of cholangitis in the United States is common bile duct obstruction as a consequence of choledocholithiasis (gallstones). Less common causes include neoplastic obstruction, postoperative obstruction after biliary intervention, benign strictures, and primary sclerosing cholangitis.[4] The decrease in biliary outflow results in biliary stasis and bacterial

proliferation. Infection results in a rapid rise in biliary pressure, which facilitates the spread of bacteria into lymphatics and the bloodstream via alterations in membrane permeability. In comparison with cholecystitis, acute cholangitis generally carries a poorer prognosis, approaching a mortality of 100% if untreated.[4,13]

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 70-1

Question 1: D.S., a 54-year-old male, presents to the hospital with a 1-week history of abdominal pain and tenderness, localized to the right upper quadrant, fever of 102.02 °F (38.9 °C), and chills. He reports nausea, with three episodes of emesis occurring in the past 24 hours. D.S. appears jaundice and reports dark-colored urine. His laboratory values are the following:

White blood cell (WBC) count, 17 × 10^3/μL
Serum creatinine (SCr), 1.1 mg/dL
Total bilirubin, 6 mg/dL
Alkaline phosphatase, 270 U/L

What evidence of cholangitis exists in D.S.? How does the presentation of cholecystitis differ from that of cholangitis?

The clinical manifestations of acute cholangitis vary, but the classic presentation involves the Charcot triad, which consists of fever, jaundice, and right upper quadrant abdominal pain. Nausea and vomiting can follow.[4,12] Fever is present in 90% of cases, and jaundice and abdominal pain occur in 60% to 70% of cases.[4] On physical examination, tenderness in the right upper quadrant and a positive Murphy's sign (inspiration inhibited by pain on palpation) are often present. A smaller percentage of patients with more severe disease, generally with gram-negative bacteremia, may present with changes in mental status and hypotension.[4] The addition of these two signs to the Charcot triad is often referred to as Reynold pentad. Laboratory findings of acute cholangitis include leukocytosis, elevated bilirubin (>2 mg/dL), and alkaline phosphatase, and mildly elevated liver transaminases.[4,14] The clinical signs and symptoms of cholangitis, as exemplified by D.S., include high fevers 102.02 °F

(38.9 °C), chills, jaundice, and right upper quadrant abdominal pain. Laboratory evidence supportive of cholangitis includes leukocytosis with WBC of 17 × 10^3/μL, increased bilirubin of 6 mg/dL, and elevated alkaline phosphatase of 270 U/L. Jaundice and significant elevations in transaminases are less common with cholecystitis compared to cholangitis.[4,12]

Diagnostic imaging for acute cholecystitis and cholangitis involves ultrasonography. Findings for acute cholecystitis may reveal pericholecystic fluid, distension of the gallbladder, thickening of the gallbladder wall, stones, and a sonographic Murphy's sign.[15] Ultrasound is less sensitive for choledocholithiasis, but it may reveal biliary dilation with stones. Hepatobiliary scintigraphy is another diagnostic tool used to identify obstruction of the cystic duct. After intravenous (IV) injection with technetium hepatobiliary iminodiacetic acid (Tc-HIDA), failure to observe gallbladder filling suggests acute cholecystitis.[6,15] Computed tomography (CT) imaging may be superior in determining the extent of biliary obstruction.[4] Endoscopic retrograde cholangiopancreatography (ERCP) is an alternative mode of imaging for cholangitis.[4,14]

ETIOLOGY

Case 70-1, Question 2: What are the most likely organisms causing infection in D.S.? What clinical specimens are helpful to identify the causative pathogen(s)?

The most common pathogens associated with acute cholangitis include *Enterobacterales* such as *E. coli*, *Klebsiella* species, and *Enterobacter* species. However, *P. aeruginosa*, skin flora (*Staphylococcus* species, *Streptococcus* species), and oropharynx bacteria may be implicated. Anaerobic organisms, commonly *Bacteroides* species, are associated with ~15% of infections, particularly in elderly patients undergoing biliary tract surgery.[4,16] The etiology of cholecystitis typically involves *E. coli*, *Klebsiella* species,

and *Enterococcus* species. Anaerobes are less commonly isolated (see Table 70-1).[4,12]

As described earlier, the stasis of bile flow results in proliferation of bacteria within the gallbladder or common bile duct. Acute cholangitis results in increased pressure within the common bile duct with dissemination of bacteria from the biliary tree to the bloodstream. Blood culture results may be positive in up to 40% of patients with symptomatic acute cholangitis.[4] Acute cholecystitis may reveal positive bile culture results in 20% to 75% of patients with symptomatic disease, whereas 59% to 93% of bile culture results have generally been found positive for acute cholangitis.[2] In contrast to cholangitis, bacteremia is unlikely with cholecystitis. The choice of antibacterial agents is largely empiric covering the aforementioned common causative pathogens.

TREATMENT

Definitive therapy for both cholangitis and cholecystitis must involve source control, using surgery, percutaneous drainage, or endoscopic intervention. Empiric antibacterial therapy should be added owing to the likelihood of secondary infection and to prevent complications. Supportive measures include fluid and electrolyte supplementation and analgesia.[4,5,12,14]

To decompress or drain the biliary ductal system in cholangitis, ERCP is used with a success rate of >90% in the treatment of cholangitis.[4] Alternatively, percutaneous transhepatic biliary drainage or endoscopic sphincterotomy can be used to drain the contents. Open surgery is a less favored option to decompress the biliary tree because it is associated with increased mortality.[4] Acute symptomatic cholecystitis requires removal of the gallbladder (cholecystectomy). The procedure of choice is laparoscopic cholecystectomy within 48 to 72 hours of onset of symptoms. Early intervention is associated with decreased morbidity and length of hospital stay compared with delayed surgical intervention.[4,12] In high-risk patients, in whom the risks outweigh the benefits of early surgery, percutaneous cholecystostomy can be performed to drain

the contents of the gallbladder. The procedure improves the clinical symptoms in 75% to 90% of patients who cannot undergo surgery. Cholecystectomy, however, should take place once the patient is stable enough for surgery.[4] For acute uncomplicated cholecystitis with no infection outside the gallbladder, antibiotics can be discontinued within 24 hours of cholecystectomy.[15]

CASE 70-1, QUESTION 3: Based on the most likely causative pathogen(s), what empiric antimicrobial therapy is recommended for D.S., given a diagnosis of cholangitis?

Empiric antimicrobial therapy for acute cholangitis and cholecystitis should be initiated after blood cultures have been collected. The empiric choice of therapy should cover enteric gram-negative pathogens, particularly *E. coli* (**Table 70-2**).[5,6] In general, the addition of anaerobic coverage is not mandatory for cholecystitis; however, it should be considered in the setting of severe cases such as acute cholangitis, biliary-enteric anastomosis, or health care–associated infections.[6] Empiric coverage for *Enterococcus* species should be considered for patients at risk for health care–associated infections, such as immunocompromised patients, patients who have required long-term hospitalization, patients who have received broad-spectrum antimicrobial therapy, or patients with valvular heart disease or prosthetic intravascular materials.[6] Antimicrobial therapy must be guided by drug pharmacokinetics and pharmacodynamics, local resistance patterns, and patient factors, such as drug allergies, renal or hepatic dysfunction, and cost.

Table 70-2
Treatment Options for Intra-Abdominal Infections

Infection	Agents and Regimens	Agent Dosing[a]
Mild-to-moderate in severity: Community-acquired perforated or abscessed appendicitis or	**Single agent** Cefoxitin Ertapenem Moxifloxacin[b]	Cefoxitin 2 g IV every 6 hours Ertapenem 1 g IV every 24 hours

Acute cholecystitis	Tigecycline **Combination** Cefazolin or Ceftriaxone or Cefotaxime or Ciprofloxacin[b] or Levofloxacin[b] + metronidazole	Tigecycline 100 mg initially, then 50 mg IV every 12 hours Cefazolin 1–2 g IV every 8 hours Ceftriaxone 1–2 g IV every 12–24 hours Cefotaxime 1–2 g IV every 6–8 hours Ciprofloxacin 400 mg IV every 12 hours Levofloxacin 750 mg IV every 24 hours Moxifloxacin 400 mg IV every 24 hours Metronidazole 500 mg IV every 8–12 hours Cefepime 1–2 g IV every 8 hours *and* Ceftazidime 1–2 g IV every 8–12 hours Piperacillin–tazobactam 3.375 g IV every 4–6 hours or 4.5 g IV every 6 hours[c] Imipenem–cilastatin 500 mg IV every 6 hours or 1 g every 8 hours Meropenem 1 g IV every 8 hours Vancomycin[d] 15–20 mg/kg IV every 8–12 hours (normal renal function) Aztreonam[e] 1–2 g IV every 6–8 hours Ceftazidime/avibactam 2.5 g IV every 8 hours or Ceftolozane/tazobactam 1.5 g IV every 8 hours + Metronidazole 500 mg IV every 8–12 hours
High risk in severity: Community-acquired acute cholecystitis with severe physiologic disturbance, advanced age, or immunocompromised state or Acute cholangitis associated with biliary-enteric anastomosis or Health care–associated intra-abdominal infections	**Single agent** Imipenem–cilastatin Meropenem Piperacillin–tazobactam **Combination** Cefepime or Ceftazidime or Ciprofloxacin[b] or Levofloxacin[b] + metronidazole	

		Imipenem–cilastatin/relebactam 1.25 g IV every 6 hours Eravacycline 1 mg/kg IV every 12 hours

IV, intravenous.

[a]Normal renal function dosing.

[b]Selection of fluoroquinolones should be based on local antibiogram or susceptibility reports.

[c]Extended infusion: 3.375 g IV every 8 hours over 4 hours.

[d]May be added to each regimen in the setting of health care–associated intra-abdominal infections (eg, methicillin-resistant *Staphylococcus aureus* or ampicillin-resistant enterococcal infection).

[e]For patients who are intolerant of β-lactams, aztreonam may be considered as an alternative agent for gram-negative coverage.

Considering their activity versus multidrug-resistant gram-negative bacilli, carbapenems generally should be reserved for infection caused by these pathogens. Vancomycin may be added empirically in health care–associated biliary infections in which ampicillin-resistant enterococci and MRSA are of concern. Linezolid or daptomycin may be considered in cases of known vancomycin-resistant *Enterococcus* species (VRE). Empiric broad-spectrum

antimicrobial regimens should be narrowed, when possible, based on culture and susceptibility findings. For mild-to-moderate community-acquired acute cholecystitis, monotherapy with cefazolin, cefuroxime, or ceftriaxone is recommended. Because of a wide prevalence of ampicillin–sulbactam-resistant *E. coli*, this agent is no longer recommended for empiric use.[6,16] Resistance to fluoroquinolones is problematic with unpredictable susceptibility of *E. coli* to ciprofloxacin and levofloxacin.[17] Current guidelines for cIAIs suggest that fluoroquinolones be considered for therapy when institutional antibiograms indicate >90% susceptibility of *E. coli*.[6] Use of aminoglycosides is not routinely recommended because of the need for therapeutic drug monitoring and potential nephrotoxicity and ototoxicity.[6] Furthermore, in comparison with other regimens, aminoglycoside-based regimens are inferior in the treatment of intra-abdominal infections.[18] However, some argue the decreased efficacy of aminoglycosides has been caused by inadequate dosing. An appropriate empiric regimen for D.S. would be piperacillin–tazobactam 3.375 g IV every 6 hours.

BILIARY CONCENTRATIONS

Case 70-1, Question 4: The physician caring for D.S. questions the need for an antibiotic that concentrates in the bile. Is there a benefit to using an antibiotic that is extensively excreted into bile?

Common bile duct obstruction prevents the entry of antibiotics into the bile, and the need for high biliary concentrations of antibiotics in the treatment of cholangitis has been debated.[19] Nagar and Berger[20] concluded that a number of antibiotics with excellent in vitro susceptibility, but poor biliary excretion, are still clinically effective. Biliary antibacterial concentrations do not correlate with an improved clinical outcome.[4] Highly biliary-excreted versus moderately biliary-excreted antibiotics have been compared.[19] Serum concentrations are more important than are biliary levels in reducing the septic

complications of biliary tract surgery. Furthermore, biliary excretion of any antibiotic is minimal in the presence of obstruction.[19]

The treatment of D.S.'s biliary tract infection must include biliary drainage. Piperacillin–tazobactam should be continued for 4 to 7 days.

PRIMARY PERITONITIS

Peritonitis is inflammation of the peritoneum as a result of infectious or chemical inflammation within the peritoneal cavity.[2,21] Infectious peritonitis can be classified as primary, secondary, or tertiary. Primary peritonitis involves the development of infection in the peritoneal cavity in the absence of other intra-abdominal pathology.[21,22] Secondary peritonitis classically results from other intra-abdominal abnormalities leading to contamination of the peritoneum with gastrointestinal (GI) or genitourinary microorganisms due to the loss of mucosal barrier integrity (eg, trauma or perforation). Tertiary peritonitis is clinical peritonitis along with signs of sepsis and multiorgan dysfunction persisting or recurring after the treatment of secondary peritonitis, often involving multidrug-resistant pathogens.[2,21] Tertiary peritonitis has a poor prognosis with a mortality rate of 30% to 64%.[23]

Primary peritonitis is also known as spontaneous bacterial peritonitis (SBP) and is most frequently identified in adults with cirrhosis and ascites. Nearly 10% to 30% of patients hospitalized with cirrhosis and ascites have SBP.[2,22,24] Primary peritonitis is associated with postnecrotic cirrhosis, chronic acute hepatitis, acute viral hepatitis, congestive heart failure, metastatic malignancy, or systemic lupus erythematosus.[2,21] In addition to advanced cirrhosis, other risk factors for primary peritonitis include GI hemorrhage, history of primary peritonitis, low protein in ascetic fluid (<1 g/dL), elevated serum bilirubin (>2.5 mg/dL), and proton-pump inhibitors.[2]

Spontaneous Bacterial Peritonitis in Patients With Cirrhosis

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with SBP may present with fever, signs of peritonitis, including abdominal pain, altered mental status, changes in GI motility, nausea, vomiting, diarrhea, or ileus.[24] Fever is common, occurring in 50% to 80% of patients.[2] Some patients have an atypical presentation or even lack symptoms.[24] The diagnosis of SBP is made on clinical presentation and examination of the peritoneal fluid via paracentesis. The ascitic fluid is tested for cell counts with WBC differential, and the presence of microorganisms is based on Gram stain and culture. Fluid analysis should be collected before the start of antibiotics. A positive ascitic fluid bacterial culture result with an elevated polymorphonuclear (PMN) count (≥250/μL) is diagnostic for SBP. Empiric treatment for SBP should be initiated with a significant elevation in ascitic fluid PMN, even if the ascitic fluid culture result is negative.[23]

ETIOLOGY AND PATHOGENESIS

CASE 70-2

Question 1: M.W., a 51-year old male with alcoholic cirrhosis, history of SBP, and significant abdominal ascites, presents with a 4-day history of fever of 101.12 °F (38.4 °C) and abdominal pain. Ascitic fluid obtained by paracentesis was cloudy, and culture of the ascitic fluid is pending. Laboratory values include ascitic fluid PMN count, 450/μL; serum WBC count, 12.2 × 10^3/μL; and total bilirubin, 4.4 mg/dL.

What organisms are likely to be cultured from M.W.'s ascitic fluid?

An estimated 70% of cases of SBP are caused by aerobic enteric organisms considered normal flora of the GI tract.[24] *E. coli* is the most common pathogen, followed by *Klebsiella pneumoniae*.[2] Other common causes of SBP include *Streptococcus pneumoniae* and other *Streptococcus* species, accounting for 20% of cases.

Enterococcus species are isolated in ~5% of cases.[24] *Staphylococcus* species, anaerobes, and microaerophilic organisms are rarely reported in community-acquired SBP. SBP is largely a monomicrobial infection.

One of the main mechanisms of pathogenesis associated with the development of SBP is bacterial translocation, which is the migration of microorganisms through the GI wall to mesenteric lymph nodes and other structures outside the intestine, including the bloodstream. Bacteria then infect the ascitic fluid by hematogenous or lymphogenous spread.[24],[25] Certain characteristics of patients with cirrhosis facilitate the pathogenesis of SBP, including bacterial overgrowth, decreased motility, structural intestinal damage, and decreased host-defense mechanisms that normally function to eliminate microorganisms. Bacterial overgrowth in the face of decreased motility and increased gut wall permeability, secondary to structural damage, facilitates subsequent systemic infection. Reduced opsonic activity and phagocytosis allow the microorganisms to escape the hosts' defenses and subsequently infect the ascitic fluid.[25] SBP with underlying cirrhosis was previously associated with a >90% mortality rate, but with the advances in antibacterial therapy, the rate has been reduced to ~30% to 40%.[2],[24] Gram-negative pathogens are associated with increased mortality compared with gram-positive pathogens.[2] Early diagnosis and effective antibacterial treatment of SBP are associated with reduced rates of mortality.[26] Patient characteristics associated with increased mortality include renal insufficiency, hypothermia, hyperbilirubinemia, and hypoalbuminemia. To decrease the rate of renal dysfunction associated with SBP, IV albumin at 1.5 g/kg within 6 hours of diagnosis and 1 g/kg on day 3 may be administered. Albumin acts as a volume expander to lessen hemodynamic changes, thereby preserving renal function. Albumin is recommended in patients with an SCr >1 mg/dL, blood urea nitrogen (BUN) >30 mg/dL, or total bilirubin >4 mg/dL.[24]

ANTIMICROBIAL THERAPY

Case 70-2, Question 2: Pending ascitic fluid culture results, what empiric antimicrobial therapy should be recommended for M.W.? What is an appropriate duration of therapy, and how should the response to therapy be monitored?

Although a positive Gram stain and culture result guides antibacterial therapy, nearly 60% of patients with signs and symptoms of SBP have negative culture results.[2,26] Initial antibacterial therapy for patients with a diagnosis of SBP is typically empiric and targeted toward the most likely pathogens, as described previously. Ampicillin plus an aminoglycoside was the traditional choice for empiric therapy; however, third-generation cephalosporins (cefotaxime and ceftriaxone) represent safer and more effective options.[27,28] A fluoroquinolone may be considered an alternative in patients with β-lactam allergies. Levofloxacin and moxifloxacin are preferred over ciprofloxacin, because of their superior activity against *S. pneumoniae*, the most commonly isolated gram-positive bacterial pathogen. Although parenteral therapy is preferred, oral fluoroquinolones may be as effective in patients with uncomplicated SBP.[27] As described earlier, aminoglycosides are not recommended in cirrhotic SBP therapy because of the risk of nephrotoxicity, and the decision whether to use fluoroquinolones should be based on institutional antibiogram reports.[24] Fluoroquinolones should be avoided if used previously for SBP prophylaxis.[29]

Antibiotic therapy is recommended until the PMN count from the ascitic fluid falls <250 cells/μL, which normally occurs within 5 days.[26] França et al[30] concluded that a 5-day course of cefotaxime for the treatment of SBP was as effective as a 10-day course. In general, follow-up fluid analysis is not necessary if clinically improving.

M.W. should receive empiric therapy with an antimicrobial agent effective against *E. coli* and other common pathogens such as *Klebsiella* species and *S. pneumoniae*. Any of the abovementioned options would be reasonable empiric choices. Therapy can continue for at least 5 days with signs of clinical improvement.

PROPHYLAXIS

CASE 70-2, QUESTION 3: After treatment is completed, should prophylactic antimicrobial therapy be initiated in M.W.?

Recurrence rates for SBP are high. Patients with cirrhosis who survive an episode of SBP have a 1-year recurrence rate of nearly 70%. Owing to the high risk of mortality from primary peritonitis, antibiotic prophylaxis should be administered to the following patients because they are considered high risk for the development of SBP: patients who have had one or more episodes of SBP; patients with cirrhosis with GI bleeding; patients with cirrhosis with ascites, who have impaired renal or liver function; or patients with cirrhosis with a low ascitic protein (<1.0 g/dL).[24]

Antibiotic prophylaxis in patients with cirrhosis is typically initiated to provide selective decontamination of the GI tract. The goal of this therapy is to reduce the burden of bacteria and subsequently prevent bacterial translocation and infection and reduce the risk of rebleeding.[24],[25] Prospective, randomized studies in subjects with cirrhosis with ascites support the use of oral antibacterial agents to reduce the rate of recurrence. The agents studied include oral norfloxacin[31] (no longer available in the United States), ciprofloxacin,[32] and trimethoprim–sulfamethoxazole.[33] Rifaximin, a nonabsorbable derivative of rifamycin, has also been shown to significantly reduce the occurrence of SBP.[34] Clinical trials have provided evidence to support the use of short-course therapy (7 days) with IV ceftriaxone 1 g/day to prevent peritonitis in hospitalized patients with cirrhosis presenting with GI hemorrhage.[25],[35] Transition to oral therapy (ciprofloxacin or trimethoprim–sulfamethoxazole) to complete 7 days is reasonable once bleeding has stopped and the patient is stable. Several cost analyses have been performed, demonstrating that prophylactic therapy in high-risk groups of patients with cirrhosis is cost-effective.[25] Long-term prophylaxis is recommended based on the significant reduction in rates of recurrence in clinical trials. However, the rising prevalence of gram-

positive bacteria and multidrug-resistant organisms parallel with concerns for gut microbiota dysbiosis question the risk versus benefit of long-term prophylaxis for SBP, particularly in vulnerable patients with cirrhosis.[36] Long-term prophylaxis in patients with low ascitic protein, elevated bilirubin, or both may also be beneficial, but it has not been associated with decreased overall infection or mortality and, therefore, is not uniformly recommended.[24,25,31–33]

Because rates of fluoroquinolone-resistant and trimethoprim–sulfamethoxazole-resistant organisms are more prevalent in patients who receive long-term prophylactic therapy, its long-term use must be considered when initiating antibacterial therapy for the treatment of new infections in this patient population.[37,38]

M.W. has cirrhosis, a previous episode of SBP, and a high total bilirubin; thus, he is at high risk for recurrence. Prophylactic antimicrobial therapy should be considered and may be a cost-effective measure. M.W. would benefit from ciprofloxacin 500 mg PO daily. The use of trimethoprim–sulfamethoxazole would depend on local resistance patterns.

Continuous Ambulatory Peritoneal Dialysis–Associated Peritonitis

PATHOGENESIS AND CLINICAL PRESENTATION

CASE 70-3

Question 1: H.M., a 33-year-old female with human immunodeficiency virus (HIV) and end-stage renal disease, has undergone continuous ambulatory peritoneal dialysis (CAPD) daily for the past year. She presents with abdominal pain and a cloudy dialysate fluid. H.M. has negligible residual urine output.

What are the most common causative organisms related to CAPD-associated peritonitis? What empiric antimicrobial therapy should be initiated? How should antimicrobial agents be administered?

Following SBP, peritoneal dialysis (PD) is another cause of primary peritonitis. Historically, an estimated 45% of patients

undergoing CAPD will experience at least one episode of peritonitis in the first 6 months of dialysis. Approximately 60% to 70% of patients exhibit peritonitis during the first year of dialysis, and recurrent infection occurs in 20% to 30% of patients.[2] CAPD-associated peritonitis is theorized to originate from contamination of the catheter by organisms of the normal skin flora, contamination of the peritoneum from an exit-site or subcutaneous-tunnel infection, contamination of the dialysate fluid, or bacterial translocation.[2] Nasal carriers of *Staphylococcus aureus* may have a higher incidence of PD-associated peritonitis.[39] Alterations in host defenses of the peritoneum may also have a role in the development of CAPD-associated peritonitis.[2]

Clinical manifestations of CAPD-associated peritonitis include abdominal pain and tenderness, which is observed in 60% to 80% of patients. Nausea and vomiting occur in ~30% to 50% of patients, whereas 10% will have diarrhea and 10% to 20% will present with fever. The diagnosis of peritonitis is made on the basis of clinical signs and symptoms along with examination of the dialysate fluid for cell counts, Gram stain, and culture. Characteristically, the dialysate fluid will be cloudy and have a WBC count >100 cells/μL (85% have >500 cells/μL) after a dwell time of 2 hours with a neutrophilic predominance (at least 50%).[2,40] A low leukocyte count may suggest a tunnel infection and eosinophilic peritonitis may represent an allergy to tubing or drug or presence of fungal and parasitic peritonitis.[3] The Gram stain result may be positive in 9% to 50% of cases, and blood culture results are typically negative.[2,41] In most cases, peritonitis is commonly caused by a single organism.[42]

ETIOLOGY

The most common causative organisms have historically involved gram-positive bacteria, accounting for 60% to 80% of isolates. Coagulase-negative *Staphylococcus* species (*S. epidermidis*) have been the most common, followed by *S. aureus* and *Streptococcus* species. Gram-negative bacilli are isolated in ~15% to 30% of cases, with *E. coli* being the most common. Other common gram-negative

organisms include *Klebsiella* species, *Enterobacter* species, *Proteus* species, and *P. aeruginosa*. Cases due to gram-negative organisms have been on the rise largely owing to contaminated water; skin, urinary, or bowel sources; and animal contacts. Nosocomial pathogens such as VRE are also increasing, and, if isolated, should raise concerns for concomitant intra-abdominal processes. Anaerobes, fungi, and mycobacteria constitute the less commonly encountered pathogens.[2]

ANTIMICROBIAL THERAPY

Antimicrobial therapy aims to resolve inflammation and preserve the function of the peritoneal membrane. In general, empiric antibiotic therapy should be directed against the most common causative organisms, both gram-positive and gram-negative organisms, until culture results of peritoneal fluid are available. Intraperitoneal (IP) delivery of antibacterial agents is the preferred route of administration for the treatment of CAPD-associated peritonitis, except in the setting of systemic sepsis. The IP route provides very high local concentrations of antibacterial agents as well as the ability to avoid a venipuncture and allow the patient to self-administer therapy at home.[40]

Empiric IP administration of antibiotics should be given when CAPD-associated peritonitis is suspected. When culture and susceptibility results are available, antibacterial therapy should be adjusted as necessary. With appropriate therapy, a clinical response should be expected within the first 48 hours.[40]

Treatment guidelines for CAPD-associated peritonitis provide a systematic approach for antimicrobial selection, dosing guidelines, and duration of therapy.[40] Dosing regimens are targeted to maintain drug concentrations above the minimum inhibitory concentration (MIC) of the causative pathogen in the peritoneal cavity fluid for majority of the dosing interval. Intermittent dosing should dwell for at least 6 hours; however, intermittent versus continuous dosing regimens have been found to be relatively equivalent in results.[43] Empiric IP therapy recommendations include vancomycin or a first-

generation cephalosporin for gram-positive coverage plus an antibacterial agent with antipseudomonal coverage.[40] Because of the increasing rates of MRSA and methicillin-resistant *Staphylococcus epidermidis*, vancomycin may be the most appropriate initial empiric agent for gram-positive organisms.[42–45] Empiric gram-negative antipseudomonal therapy can be initiated with a third-generation cephalosporin (ceftazidime) or an aminoglycoside. Alternatively, cefepime, piperacillin–tazobactam, or a carbapenem may also be used.[2,40,46] For patients who are intolerant of β-lactams, aztreonam may be considered as an alternative agent for gram-negative coverage.[40,46] IP fluoroquinolones represent an option for CAPD-associated peritonitis; however, avoidance of fluoroquinolone use should be considered when local fluoroquinolone-resistant rates are >10%.[47,48]

Refractory peritonitis, presence of cloudy effluent after 5 days of IP therapy, may require removal of the catheter, as well as cases of relapse and recurrent and repeat peritonitis. When concomitant *S. aureus* exit-site or tunnel infection is identified, the infection usually necessitates the removal of the dialysis catheter. Vancomycin is recommended for MRSA. Conversely, cefazolin alone is adequate for methicillin-susceptible *Staphylococcus aureus* (MSSA). Coagulase-negative *Staphylococcus* species do not require prompt catheter removal because they typically respond well to antimicrobial therapy. Methicillin resistance is common for *S. epidermidis*; thus, vancomycin is normally used. *Enterococcus* species or *Streptococcus* species should be treated with ampicillin if susceptible. Vancomycin should be used for ampicillin-resistant enterococcus; however, VRE requires treatment with daptomycin, linezolid, or quinupristin–dalfopristin. In the case of peritonitis where the culture result was negative with clinical improvement after 3 days of empiric coverage, a single agent directed toward gram-positive organisms may be continued for a total of 2 weeks.[40]

When a single gram-negative organism is cultured (eg, *E. coli*, *Klebsiella* species, or *Proteus* species), therapy can be narrowed based on susceptibility. Isolation of *P. aeruginosa* most often indicates a severe infection, involving the dialysis catheter (exit site

and tunnel infection) with a high rate of relapse and treatment failure, in which case catheter removal is recommended.[2] Therapy options include an antipseudomonal β-lactam such as ceftazidime, cefepime, or piperacillin–tazobactam. Double coverage with antipseudomonal agents (using a fluoroquinolone or an aminoglycoside) pending susceptibilities may be needed in the setting of hemodynamic instability; however, ongoing dual therapy has not been found to be of benefit.[2] In general, IP β-lactam antimicrobials achieve peritoneal fluid concentrations exceeding typical minimum inhibitory concentrations for most commonly encountered facultative gram-negative and anaerobic bacteria.[40],[49],[50]

Polymicrobial peritonitis is uncommon and may indicate a more complicated intra-abdominal process requiring surgery if clinical response is not obtained from medical management. Anaerobic coverage is recommended. Duration of therapy generally lasts 2 to 3 weeks.[2] **Table 70-3** lists antimicrobial dosing guidelines for the treatment of peritonitis associated with CAPD.[40]

Table 70-3
Intraperitoneal Antibiotic Dosing Recommendations for Patients With Peritoneal Dialysis

	Intermittent Dosing[a]	Continuous Dosing[b] (mg/L)	
		LD	MD
Amikacin	2 mg/kg daily	25	12
Amoxicillin			150
Ampicillin			125
Ampicillin/sulbactam	2 g/1 g every 12 hours	750–100	100
Aztreonam	2 g daily	1000	250
Cefazolin	15–20 mg/kg daily	500	125
Cefepime	1000 mg daily	250–500	100–125
Cefotaxime	500–1000 mg daily		
Ceftazidime	1000–1500 mg daily	500	125
Ceftriaxone	1000 mg daily		
Ciprofloxacin			50
Clindamycin			600 mg/bag
Daptomycin		100	20
Fluconazole	200 mg every 24–28 hours		
Gentamicin	0.6 mg/kg daily	8	4
Imipenem/cilastatin	500 mg in alternate exchange	250	50
Meropenem	1000 mg daily		
Penicillin G		50,000 units/L	25,000 units/L
Piperacillin/tazobactam		4 g/0.5 g	1 g/0.125 g
Polymyxin B			300,000 unit (30 mg)/bag
Quinupristin/dalfopristin	25 mg/L in alternate exchange[c]		
Tobramycin	0.6 mg/kg	3 mg/kg	0.3 mg/kg
Vancomycin	15–30 mg/kg every 5–7 days[d]	30 mg/kg	1.5 mg/kg/bag
Voriconazole	2.5 mg/kg daily		

Empiric doses for patients with residual renal function (>100 mL/day urine output) should be increased by 25%.

LD, loading dose; MD, maintenance dose.

[a]Per exchange, once daily.

[b]All exchanges.

[c]Given in conjunction with 500 mg intravenously (IV) twice daily.

[d]Supplemental doses may be needed for patients with ambulatory peritoneal dialysis (APD).

Source: Li PK, Szeto CC, Piraino B, et al. ISPD Peritonitis recommendations: 2016 update on prevention and treatment. *Perit Dial Int*. 2016;36(5):481–508. © 2016 SAGE Publications. Reprinted by permission of SAGE Publications, Inc.

An example of an appropriate ‘empiric’ regimen for H.M may include vancomycin plus cefepime or an aminoglycoside given IP.

The clinician should monitor culture and susceptibility results to adjust therapy based on guidelines, local sensitivity patterns, and therapeutic response.

FUNGAL CONTINUOUS AMBULATORY PERITONEAL DIALYSIS–ASSOCIATED PERITONITIS

CASE 70-3, QUESTION 2: Two years later, H.M. presents with abdominal pain and cloudy dialysate fluid. *Candida albicans* is cultured from the dialysate fluid. No other organisms are present. How should H.M. be treated?

Fungal peritonitis is a rare complication of CAPD that is associated with significant morbidity and mortality. The rate of mortality in fungal peritonitis is ~25%.[40] Considering the high rate of failure of therapy, patients with CAPD with fungal peritonitis should have their catheters removed.[44] Patients who have received prolonged or multiple courses of antibiotics; are on immunosuppressant therapy for a malignancy, a transplant, or an inflammatory disease; or have a postoperative or recurrent intra-abdominal infection are at increased risk for fungal peritonitis and should be treated with antifungals.[2],[5],[51] Most cases are caused by *Candida* species, most commonly *C. albicans*; however, an increase in infection attributable to non-albicans species has emerged in many areas.[51] Empiric antifungal therapy should be broad and include most *Candida* species; echinocandins such as caspofungin, micafungin, or anidulafungin are the empiric drugs of choice. Amphotericin B may be administered via IV or IP, but when given IP, conventional amphotericin B is very irritating to the peritoneum.[40] The azole antifungal agents can be administered orally or via IV or IP. Fluconazole is active against *C. albicans*, but it has dose-dependent activity against certain types of non-albicans species, such as *C. glabrata*. In general, fluconazole is the drug of choice for *C. albicans*; however, other options, such as a polyene or echinocandin, may be needed for azole-resistant *Candida* species. Therapy should continue for a minimum of 2 weeks after catheter removal, and the

total duration may be based on severity and clinical response.[40] Owing to the azotemic state of the patient and its high renal elimination, flucytosine should not be used because of the risk of severe toxicity to the colon and bone marrow.[2]

H.M.'s treatment should include temporary catheter removal and administration of antifungal agents. Antifungal therapy with oral fluconazole 400 mg daily should be continued for at least 14 days.

SECONDARY PERITONITIS

Pathogenesis and Epidemiology

Secondary peritonitis usually occurs after fecal or urinary contamination of the peritoneal cavity or its surrounding structures.[3] The process leading to an infection commonly includes an acute perforation associated with appendicitis, diverticulitis, the uterus, neoplasm, and inflammatory bowel disease (IBD). Secondary peritonitis can also result from postoperative or posttraumatic perforation of the GI or genitourinary tract related to blunt trauma or ingestion of foreign material.[52,53]

Localization of infection without eradication of bacteria results in IP or visceral abscesses. IP abscesses occur most often in the right lower quadrant in association with appendicitis or a perforated peptic ulcer. Other causes can include diverticulitis, pancreatitis, IBD, trauma, and abdominal surgery. Visceral abscesses generally are found in the pancreas but may also occur in the liver, spleen, or kidney.[2]

Mortality with secondary peritonitis can be as high as 68%.[54] Timely source control with surgical intervention is imperative for clinical success of infections resulting from secondary peritonitis. Management with appropriate antimicrobial therapy, intensive care support, and the overall health of the patient are also critical for the outcome.[53]

Clinical Presentation and Diagnosis

CASE 70-4

QUESTION 1: R.C., a 48-year-old male, presents with severe abdominal pain and nausea. He states he has been taking nonsteroidal anti-inflammatory drugs (NSAIDs) for joint pain daily for the past 2 weeks. An esophagogastroduodenoscopy reveals a perforated peptic ulcer. Significant vital signs include a temperature of 101.66 °F (38.7 °C) and tachycardia (pulse, 105 beats/minute). Bowel sounds are absent. Pertinent laboratory values include WBC count, 16.5 × 10^3/μL and BUN, 34 mg/dL.

What signs and symptoms of secondary peritonitis does R.C. display?

Making the diagnosis of a localized intra-abdominal infection may be difficult, despite the presence of signs and symptoms typical of infection. Moderate-to-severe abdominal pain with anorexia, nausea, and vomiting are commonly experienced. Fevers with or without chills, tachycardia, sparse urination secondary to fluid loss into the peritoneum, faint or absent bowel sounds, and abdominal distension may accompany primary GI symptoms associated with peritonitis. Inflammation around the intestines and peritoneal cavity results in local paralysis and reflex rigidity of the abdominal wall muscles and the diaphragm, causing rapid and shallow respirations.[2] These signs are usually accompanied by an elevated WBC count with a predominance of neutrophils (left shift). The hematocrit (Hct) and BUN may be elevated as a result of dehydration. Initially, patients are usually alkalotic owing to emesis and hyperventilation, but in the later stages of peritonitis, acidosis usually occurs. Untreated or partially treated peritonitis can result in generalized sepsis and hypovolemic shock, in addition to a gradual development of IP abscesses. Therefore, patients with a sudden turn in disposition after treatment and recovery from peritonitis or abdominal surgery should be assessed for IP abscess formation.[3,2]

R.C. is likely to have a community-acquired intra-abdominal infection suggestive of a secondary peritonitis resulting from an acute perforated peptic ulcer after NSAID use for 2 weeks. His current clinical status is highlighted by severe abdominal pain and

nausea, fever with tachycardia, a significant elevation in WBC, and signs of dehydration with a BUN of 34 mg/dL.

CASE 70-4, QUESTION 2: Given these findings, what are the most likely pathogens for R.C.'s secondary peritonitis?

ETIOLOGY

The normal flora consistent with the perforated segment of the GI tract determines the most likely pathogens, consisting of both aerobes and anaerobes (anaerobes become more prevalent the more distal the source).[55] In general, the stomach and small bowel consist of few microbes, such as *Candida* species, lactobacilli, and oral streptococci, in the fasting state. However, the number and variety of gastric microbiota can increase with meals, achlorhydria (use of H_2 blockers or proton-pump inhibitors), obstruction, and presence of blood.[2] The most common facultative bacterium is *E. coli*, which is found in ~50% of cultures. A variety of other facultative gram-negative bacteria include *Klebsiella* species, *P. aeruginosa*, *Proteus* species, and *Enterobacter* species (**Table 70-4**).[3,56–59] *E. coli*, enterococci, and a predominant presence of obligate anaerobes, including *Bacteroides fragilis*, *Prevotella* species, *Peptococcus* species, *Peptostreptococcus* species, and *Fusobacterium* species, are found in the ileum and colon of the large bowel. *B. fragilis* is the most frequently isolated obligate anaerobe after perforation of the colon.[2,60] Anaerobic cocci (*Peptostreptococcus*) and facultative gram-positive cocci, such as streptococci, are also isolated.[2,6,57,60] *Enterococcus* species are isolated less frequently.[2,6,57,60] *B. fragilis* and *E. coli* are the most common pathogens found in blood culture samples after bacteremia related to an intra-abdominal infection.[2] Highly antibiotic-resistant strains of *P. aeruginosa*, Enterobacterales-producing ESBLs or carbapenemases, *Acinetobacter* species, and *Enterococcus*, as well as *Candida* species, are often isolated from hospitalized patients who experience secondary peritonitis.[2,6]

Table 70-4
Bacteriology of Intra-Abdominal Infections

Bacteria	Patients (%)
Facultative and Aerobic Gram Negatives	
Escherichia coli[a]	71
Klebsiella species	14
Pseudomonas aeruginosa	14
Proteus mirabilis	5
Enterobacter species	5
Anaerobes	
Bacteroides fragilis[a]	35
Other *Bacteroides* species	71
Clostridium species	29
Prevotella species	12
Peptostreptococcus species	17
Fusobacterium species	9
Eubacterium species	17
Aerobic Gram Positives	
Streptococcus species	38
Enterococcus faecalis	12
Enterococcus faecium	3
Staphylococcus aureus	4

[a]Most common in community-acquired intra-abdominal infections.

Source: Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by Surgical Infection Society and the Infectious Diseases Society of America. *Clin Infect Dis*. 2010;50(2):133–164. Reproduced by permission of Infectious Diseases Society of America; Paterson DL, Rossi F, Baquero F, et al. In vitro susceptibilities of aerobic and facultative Gram-negative bacilli isolated from patients with intra-abdominal infections worldwide: the 2003 Study for Monitoring Antimicrobial Resistance Trends (SMART). *J Antimicrob Chemother*. 2005;55(6):965–973.

Gram stain and culture do not need to be routinely obtained in community-acquired intra-abdominal infections before the initiation of antimicrobial therapy. It may be useful in health care–associated infections for detection of gram-positive cocci, yeast, or multidrug-resistant pathogens.[2,6] The presence of pleomorphic gram-negative bacilli, a strong odor, or tissue gas is strongly suggestive of infection with anaerobes, particularly *B. fragilis.*

R.C.'s secondary peritonitis is likely due to the presence of a facultative gram-negative organism, such as *E. coli*, *Proteus* spp., *Klebsiella* spp., or *Enterobacter* spp., or possibly an obligate anaerobe, such as *B. fragilis*. R.C. does not present with a history of hospitalization or recent receipt of broad-spectrum antimicrobials; therefore, an infection caused by more resistant health care–associated pathogens (eg, *P. aeruginosa*, ESBLs, carbapenemases) is less likely.

Case 70-4, Question 3: What empiric antimicrobial therapy is appropriate for R.C. at this time?

Antimicrobial Therapy

EMPIRIC THERAPY

Therapy for secondary peritonitis should include early administration of antimicrobial agents directed at facultative gram-negative bacteria and obligate anaerobes, fluid therapy, and support of vital organ function, as well as source control measures. Antibiotics should be administered within 1 hour of presentation of septic shock and within 8 hours of hospital admission in those with stable hemodynamic or organ status.[6] Adequate source control involving surgical debridement and drainage, in conjunction with appropriate antimicrobial therapy, decreases morbidity and mortality and should always be performed when possible.[2,3,61] In general, when an intra-abdominal infection is suspected, antimicrobial agents should be started immediately after appropriate specimens (eg, blood, peritoneal fluid) have been obtained and before any surgical

procedures are performed.[2,3,6,62] The parenteral route should be used to ensure adequate systemic and tissue concentrations, especially in patients in whom shock or poor perfusion of the muscles or GI tract precludes the use of oral administration. Table 70-2 outlines dosing recommendations for antibiotics commonly used in the treatment of intra-abdominal infections.

For mild-to-moderate community-acquired infections, empiric monotherapy with ertapenem, moxifloxacin, tigecycline, or cefoxitin is recommended. Ertapenem provides coverage against gram-positive, gram-negative, and anaerobic organisms with the notable exceptions of *Acinetobacter* spp., *P. aeruginosa,* and *Enterococcus* spp. In comparative trials of ertapenem versus piperacillin–tazobactam, the two agents were shown to be similar in efficacy and safety.[63–65] Moxifloxacin has coverage against gram-positive and gram-negative aerobic organisms (excluding *P. aeruginosa*), in addition to anaerobic organisms, and penetrates well into inflamed GI tissue, peritoneal exudates, and abscesses.[59,66,67] Earlier concerns for resistance among *Bacteroides* species to moxifloxacin were reevaluated in recent studies and moxifloxacin was found to be a safe and effective monotherapy option for mild-to-moderate community-acquired cIAI.[6,57,68,69] However, moxifloxacin should be used cautiously in infections with recent fluoroquinolone use owing to concerns of acquired bacterial resistance.

Tigecycline offers added in vitro activity against resistant pathogens such as MRSA, VRE, and penicillin-resistant *S. pneumoniae*; however, tigecycline lacks activity against *Proteus* species and *P. aeruginosa*. Caution should be practiced when using tigecycline for severe infections, including cIAI because the U.S. Food and Drug Administration announced a boxed warning of increased risk for mortality and noncure rates. Therefore, the use of tigecycline should be considered when alternative antibiotic options are not available. Cefoxitin is a cephamycin antibiotic that covers gram-positive, gram-negative, and anaerobic bacteria. Owing to concerns of increasing resistance from anaerobes, most notably *B. fragilis,* cefoxitin has fallen out of favor compared to other guideline-recommended agents for use as monotherapy.[70] Combination

therapy with either a cephalosporin or a fluoroquinolone (ciprofloxacin or levofloxacin) plus metronidazole is also reasonable.[6]

For severe community-acquired intra-abdominal infections, meropenem, imipenem–cilastatin, and piperacillin–tazobactam are empiric monotherapy options that may be used. An antipseudomonal third- or fourth-generation cephalosporin, fluoroquinolone (ciprofloxacin or levofloxacin), or aztreonam in combination with metronidazole represent alternative options for severe infections.[6,63]

Empiric use of ampicillin–sulbactam is no longer recommended for cIAIs because of increasing rates of *E. coli* resistance.[6,71] In addition, clindamycin and cefotetan are not recommended for community-acquired cIAI because of rising resistance rates from *B. fragilis*. The association of clindamycin with *Clostridioides difficile*–associated diarrhea has also resulted in the use of other options.[6,56,63–65,72,73] With the risk of nephrotoxicity and ototoxicity with aminoglycosides, safer agents are now considered first-line treatment options. Caution should be taken when using fluoroquinolones empirically, particularly if hospital antibiograms indicate <90% susceptibility of *E. coli* because fluoroquinolone-resistant *E. coli* has become more common in the community.[6] Susceptibility patterns within the community and institutional antibiograms may assist with selection of optimal empiric antimicrobials when managing community-acquired cIAIs.

Tertiary peritonitis is described as persistent peritonitis with systemic signs of sepsis even after appropriate management of the infection has been initiated.[2] As a health care–associated infection, tertiary peritonitis often presents in critically ill or immunocompromised patients where adequate source control may be improbable. With tertiary peritonitis, pathogens can vary from those that are less virulent such as enterococci, including VRE, coagulase-negative *Staphylococcal* species, and *Candida* species to the more resistant health care–associated pathogens with little to no antibiotic options. Empiric use of meropenem, imipenem–cilastatin, or piperacillin–tazobactam[6] should be reserved for health care–associated infections in cases of sepsis and presumed or documented multidrug-resistant pathogens.

Multiple new antibiotics with activity against resistant pathogens were recently approved for the treatment of cIAI (see Table 70-2).[74,75] Ceftolozane/tazobactam, ceftazidime/avibactam, meropenem/vaborbactam, and imipenem–cilastatin/relebactam offer in vitro activity against challenging resistant gram-negative pathogens, including ESBLs and AmpC-producing *Enterobacterales* and multidrug-resistant *P. aeruginosa*.[76,77,78,79] Ceftazidime/avibactam and imipenem–cilastatin/relebactam also have in vitro activity against *K. pneumoniae* carbapenemases. Because they lack adequate anaerobic coverage on their own, both ceftolozane/tazobactam and ceftazidime/avibactam must be combined with metronidazole when treating an intra-abdominal source. Eravacycline is a new synthetic fluorocycline antibiotic that covers pathogens commonly implicated in intra-abdominal infections including enterococci, ESBL-producing *Enterobacterales*, *Acinetobacter baumannii*, and anaerobes.[80]

R.C. should receive antimicrobial therapy with activity against facultative gram-negative bacteria and anaerobes, including *B. fragilis.* Ertapenem 1 g IV every 24 hours would be an appropriate treatment for R.C.'s mild-to-moderate cIAI.

ENTEROCOCCAL INFECTION

CASE 70-5

QUESTION 1: B.B. is a 58-year-old, nonobese female with gangrene of the bowel. One day after undergoing surgical resection of the duodenum, she has a fever of 102.02 °F (38.9 °C), shaking chills, and abdominal pain. Laboratory values include a WBC count of 18.4 × 10^3/μL and creatinine of 1.1 mg/dL. B.B.'s peritoneal fluid cultures grew *E. coli*, *B. fragilis*, *C. albicans*, and *Enterococcus*. Blood culture results are negative. She is currently receiving ertapenem 1g IV every 24 hours.

Should B.B. receive additional antimicrobial therapy active against *Enterococcus*?

Although *Enterococcus* is commonly cultured in patients with secondary peritonitis, its pathogenicity has been questioned.

Enterococcus can cause serious infections (eg, endocarditis, urinary tract infections), but it is less virulent in the setting of polymicrobial infections such as intra-abdominal infections.

An important issue is whether empiric treatment should include antibiotics with activity against *Enterococcus.* Some investigators believe that *Enterococcus* species are commensal organisms that need not be treated in most clinical settings. They point to clinical studies in which antibiotic regimens lacking in vitro activity against *Enterococcus* have been successful. The pathogenicity of *Enterococcus* lies in its ability to enhance the formation of abscesses.[2,3] The presence of enterococci suggests active disease; however, use of anti-enterococcal antibiotics has not shown to improve outcomes.[3,81]

In general, coverage is warranted if *Enterococcus* is present in blood cultures or is the sole organism on culture.[2,6] Anti-enterococcal therapy is recommended in patients with nosocomial or health care–associated infections,[6] particularly those who received antibiotics selecting for *Enterococcus* spp. (eg, cephalosporins), are immunocompromised, have postoperative infection, or have valvular heart disease or prosthetic intravascular materials.[6] If susceptible, *Enterococcus* species should be treated with ampicillin or piperacillin/tazobactam. Vancomycin should be reserved for ampicillin-resistant enterococcus, whereas VRE can be treated with linezolid or daptomycin. Because B.B.'s blood culture results are negative and ascitic culture has demonstrated mixed pathogens, *Enterococcus* coverage may not be necessary. B.B. should be treated with an antimicrobial regimen that has activity against gram-negative pathogens and anaerobes

Case 70-5, Question 2: Should B.B.'s antimicrobial therapy include an agent with antifungal activity?

ANTIFUNGAL THERAPY: TREATMENT OF CANDIDA

The need to treat *Candida* species as a solitary isolate or as part of a polymicrobial infection is controversial. Certainly, *Candida* has the

potential to cause peritonitis, IP abscesses, and subsequent candidemia. Mortality resulting from *Candida* peritonitis ranges from 25% to 60%.[82] Risk factors for *Candida* peritonitis include recent abdominal surgery; GI tract perforation, particularly in those untreated within the first 24 hours; surgical drains; IV and urinary catheters; severe sepsis; and colonization by *Candida* species.[82,83] Significance of intra-abdominal candidiasis worthy of treatment rises when *Candida* species are isolated surgically or directly from an intra-abdominal collection (eg, within 24 hours of drain placement) in patients with severe community-acquired or health care–associated infections.[6,84] This may include patients who recently received immunosuppressive therapy for neoplasm; have a perforated gastric ulcer while on acid suppression; have a malignancy, transplantation, or inflammatory disease; or a postoperative or recurrent intra-abdominal infection.

Echinocandins and azoles are initial options for fungal peritonitis.[6,21] Concerns about the toxicity of conventional amphotericin B have limited the use of this agent. Fluconazole is considered an appropriate drug of choice for *C. albicans*.[6] For *C. glabrata* or other fluconazole-resistant species, an echinocandin (caspofungin, micafungin, or anidulafungin) or an amphotericin product is an appropriate option.[6] If critically ill, initial therapy with an echinocandin is recommended.

Therapy with an antifungal agent such as fluconazole 400 mg daily is acceptable for B.B. and the *C. albicans* can be isolated.

CASE 70-5, QUESTION 3: The surgical resident decides to continue ertapenem for the treatment of B.B.'s intra-abdominal infection. Should culture and susceptibility results be used to monitor for anaerobic activity?

ANAEROBIC BACTERIA

With the introduction of broad-spectrum antimicrobial agents with in vitro activity against *B. fragilis* and a significant problem of increasing resistance, the choice of a specific anti-anaerobic agent has become more complex. Multiple mechanisms of resistance are encountered,

and resistance rates differ among various geographic areas in the United States. Although *Bacteroides* resistance to metronidazole is rare,[21,85] resistance to clindamycin has increased substantially.[21] Although the carbapenems and the β-lactamase inhibitor combinations are exquisitely active against *Bacteroides*, occasional resistance has been reported.

Because most anaerobes are cultured in the setting of mixed flora, isolation of individual components of a complex mixture can be time consuming. In addition, most anaerobes are very slow growing, and it may take days to weeks for a definitive culture and susceptibility report. If specimens are not collected and transported in optimal media or in a timely manner, inaccurate or misleading results may be reported. The methods for susceptibility testing of anaerobic bacteria are not well standardized, and many hospital laboratories do not have resources to perform extensive culture and susceptibility testing. Routine cultures rarely impact the choice of antibiotic regimen, and thus the empiric choice of therapy usually determines the outcome.[86] Routine susceptibility testing for patient-specific cases is not recommended because of the prolonged time needed to achieve results, but it may be useful when resistant organisms are suspected or high-risk patients have been identified.[87]

Intra-Abdominal Abscess

CASE 70-6

Question 1: R.K. is a 28-year-old female with a history of diverticulitis who presents with abdominal pain and distension, fever, and chills. An intra-abdominal abscess is visualized by CT scan.

How did this abscess develop? What considerations should be taken into account in the selection of appropriate antimicrobial agents?

Abscesses are collections of necrotic tissue, bacteria, and WBCs that form during a period of days to years. They generally result from chronic inflammation and the body's attempt to localize organisms and toxic substances by the formation of an avascular fibrous wall.

This process isolates bacteria and the liquid core from opsonins and antimicrobial agents.

MICROBIOLOGY

Pathogens encountered in intra-abdominal abscesses often include facultative aerobic gram-negatives (eg, *E. coli*) and obligate anaerobes (eg, *B. fragilis*).[52] Mixed infections involving *E. coli* or enterococci with *B. fragilis* have been associated with a synergistic mechanism responsible for late IP abscess development.[88,89]

ANTIMICROBIAL THERAPY

Abscesses pose a therapeutic challenge because they typically contain large bacterial inocula that are likely to include subpopulations of resistant bacteria.[61] Furthermore, the rate of penetration of antibiotics into abscesses is hindered by the low surface-to-volume ratio, low pH, and decreased permeability. Although percutaneous drainage or surgical debridement of R.K.'s abscess is crucial, adjunctive therapy with antimicrobial agents is warranted. The optimal antimicrobial agent should penetrate into the abscess in adequate concentrations and have an adequate spectrum of activity.[21,61] R.K. should be placed on an antimicrobial regimen, such as piperacillin–tazobactam 3.375 g IV every 6 hours, that covers gram-negative bacteria and anaerobes.

INFECTIONS AFTER ABDOMINAL TRAUMA AND POSTOPERATIVE COMPLICATIONS

Risk factors for infection after penetrating abdominal trauma include the number, type, and location of injuries; the presence of hypotension; large transfusion requirements; prolonged operation; advanced age; and the mechanism of injury.[90]

Most investigators stress the importance of instituting antimicrobial therapy as close to the time of trauma as possible. Bozorgzadeh et

al[91] demonstrated a significant reduction in the incidence of postoperative infections when antibiotics were administered before surgical repair of the penetrating abdominal trauma.

Penetrating Trauma

CASE 70-7

Question 1: T.I., a 19-year-old male, is admitted to the emergency department within 1 hour of sustaining a gunshot wound to the stomach and colon. He is to undergo emergency laparotomy.

What antimicrobial therapy is appropriate at this time?

As with other types of intra-abdominal infections, antibiotics active against both aerobic and anaerobic pathogens should be used.

Anti-infective therapy has been studied in patients who have sustained penetrating trauma to the abdomen (usually from knife or gunshot wounds). In several comparative trials, single-drug therapy with cefoxitin was as effective as the combination of clindamycin or metronidazole plus an aminoglycoside.[92] In evaluating these studies, however, it is important to note that most patients did not sustain injuries to the colon, where the risk of infection is highest. Although the age of this patient suggests he would be more likely to tolerate aminoglycoside therapy, monotherapy with cefoxitin or one of the β-lactamase inhibitor combinations would be appropriate.

Consensus guidelines regarding the duration of therapy were published by the Eastern Association for the Surgery of Trauma (EAST) Practice Management Group. These investigators reviewed all literature from 1976 to 1997 regarding the duration of antimicrobial use after penetrating abdominal trauma. They concluded that antimicrobial use should not exceed 24 hours in this patient population.[90]

Case 70-7, Question 2: How long should antibiotic therapy be administered to T.I.?

The shortest duration of antimicrobial therapy that has been shown to be effective has been 12 hours with the possibility that a short course (eg, 48 hours) is as efficacious as a 5- to 7-day course if antimicrobial therapy is promptly instituted.[6] Several other trials have confirmed that no additional benefit exists in providing a longer treatment duration.[6,86,90,93–95]

Because antimicrobial therapy carries a risk of adverse reactions, development of resistance, and unnecessary costs, short-term therapy seems warranted as long as it is instituted soon after the injury.[90,96] If the initial dose of antibiotic is administered >3 to 4 hours after injury, therapy should be continued for 3 to 7 days because the incidence of infection in this circumstance is high.

Antimicrobial therapy was instituted soon after T.I. sustained the colonic injury; therefore, a short course of antimicrobial therapy is appropriate. Therapy should be continued for 24 hours.

Appendectomy

CASE 70-8

QUESTION 1: S.R. is a 12-year-old female with a 2-day history of periumbilical pain migrating to the right lower quadrant, abdominal distension, fever of 102.2 °F (39 °C), diarrhea, and decreased bowel sounds. Her WBC count is 15.8 × 10^3/μL. A presumptive diagnosis of acute appendicitis is made.

What antimicrobial therapy is indicated?

Clinical manifestations commonly encountered with acute appendicitis include right lower quadrant abdominal pain, rebound tenderness, and low-grade fever complicated by nausea, vomiting, and anorexia.[2,6,40]

A variety of antimicrobial agents are effective in the treatment of acute appendicitis.[97–101] Antimicrobial therapy selection for uncomplicated appendicitis can follow those recommended for community-acquired intra-abdominal infection where therapy for <24 hours is sufficient.[6] Patients with gangrenous or perforated appendices are associated with the highest risk of infection. In

several well-designed, randomized, placebo-controlled trials, therapy with imipenem–cilastatin, β-lactams, and β-lactamase inhibitor combinations has been found to be as effective as the combination of clindamycin or metronidazole plus an aminoglycoside.[30,98,100] Patients with gangrenous or perforated appendices who were afebrile for 48 hours have been treated for durations ranging from a single dose[101] to 3 to 5 days.[99]

S.R. should receive a preoperative dose of β-lactam antimicrobials with activity against facultative gram-negative and anaerobic bacteria, such as cefoxitin alone or cefazolin plus metronidazole (see Table 70-2). Cost, potential side effects, and ease of administration guide selection of a specific agent. If a gangrenous or perforated appendix is found during surgery, antimicrobial therapy should be continued for a minimum of 3 to 5 days or until S.R. has been afebrile for 48 hours.

DURATION OF ANTIMICROBIAL THERAPY

Recommendations for the duration of therapy for intra-abdominal infection vary from 4 to 7 days and depend primarily on the patient's clinical response to therapy and the need for surgical drainage.[6] In general, antimicrobial therapy should be continued until resolution of signs of infection, including return of WBC count to normal and elimination of fever. The STOP-IT trial (Trial of Short-Course Antimicrobial Therapy for Intra-Abdominal Infection) published in 2015 evaluated the composite outcome of surgical-site infection, recurrent intra-abdominal infection, or death within 30 days in patients with cIAI and adequate source control randomized to either antibiotic therapy until 2 days after the resolution of fever, leukocytosis, and ileus with a maximum of 10 days of therapy or a fixed antibiotic course of 4 ± 1 calendar days. The study found that in patients who had undergone an adequate source control procedure, there was no difference in outcomes between the groups, suggesting that a fixed course of ~4 days should be recommended after source

control is achieved.[102] Another randomized clinical trial evaluated duration of therapy for postoperative intra-abdominal infections in patients in the ICU who are critically ill. This study concluded that a longer course of antibiotics (15 days) was not associated with any clinical benefit when compared to a short course of antibiotics (8 days).[103] Without adequate source control, antimicrobial therapy will likely need to be continued for longer durations.

Urinary Tract Infections

Douglas N. Fish

CORE PRINCIPLES		CHAPTER CASES
1	Urinary tract infection (UTI) is usually bacterial in etiology, may be either acute or chronic, and may affect any part of the upper or lower urinary system. UTI is classified as either uncomplicated or complicated based on patient characteristics and on the clinical setting in which the infection is acquired (eg, community-acquired vs health care–acquired infection).	**Case 71-1 (Questions 1–6)** **Case 71-2 (Questions 1, 2)**
2	Uncomplicated UTI occurs in females who are otherwise healthy and have normal urinary tract structure and function. These infections are primarily caused by *Escherichia coli* (75%–95% of infections) and other gram-negative bacilli, as well as gram-positive	**Case 71-1 (Questions 1–3)**

	organisms such as *Staphylococcus saprophyticus* and *Enterococcus.*	
3	Symptoms commonly associated with lower UTI (eg, cystitis) include dysuria, frequent urination, suprapubic pain, and hematuria. Patients with upper tract infection (eg, acute pyelonephritis) often present with similar findings as well as loin pain, costovertebral angle tenderness, fever, chills, nausea, and vomiting.	**Case 71-1 (Questions 1, 2)** **Case 71-5 (Questions 1–3)**
4	The cornerstone of effective UTI treatment is appropriate selection and use of antibiotics. Resistance among *E. coli* and other uropathogens is increasing and is an important consideration in antibiotic selection. Consensus clinical guidelines recommend trimethoprim–sulfamethoxazole (TMP-SMX) for 3 days, nitrofurantoin for 5 days, or a single dose of fosfomycin as preferred first-line antibiotics for treatment of acute uncomplicated cystitis in females.	**Case 71-1 (Questions 1–6)** **Case 71-2 (Question 1), Tables 71-1–71-3**
5	Fluoroquinolones are commonly used for treatment of UTI and are highly effective. However, concerns regarding increased resistance and potential adverse effects limit the use of fluoroquinolones in uncomplicated UTI to patients unable to receive other preferred agents because of drug resistance, allergies, or other	**Case 71-1 (Question 3)** **Case 71-2 (Questions 1, 2)** **Case 71-3 (Question 1), Tables 71-1–71-3**

	contraindications. Similar recommendations restrict the use of β-lactam antibiotics for uncomplicated UTI.	
6	Complicated UTI is associated with abnormalities of the urinary tract that interfere with normal urine flow or function; males, children, patients with diabetes, pregnant females, and hospitalized patients are examples of commonly affected populations. Complicated infections are frequently caused by drug-resistant gram-negative bacilli or other pathogens with reduced antibiotic susceptibility. Antibiotic selection for complicated UTI should be guided by culture and susceptibility testing, and patients usually require longer durations of antibiotic therapy (7–14 days).	**Case 71-1 (Questions 1–4)** **Case 71-2 (Question 1)** **Case 71-4 (Question 1)** **Case 71-10 (Question 1)** **Case 71-11 (Questions 1–3)**
7	Pyelonephritis may be more severe in presentation and often associated with bacteremia and other complications. However, most cases are uncomplicated and can be treated on an outpatient basis with oral antibiotics such as fluoroquinolones. Patients who cannot take oral antibiotics or who are clinically unstable should be hospitalized for initial treatment with intravenous antibiotics.	**Case 71-5 (Questions 1–5), Tables 71-1, 71-2, 71-5**
8	Recurrent UTI may be caused by either reinfection or relapse because of	**Case 71-6 (Questions 1–3, 6–8)**

	treatment failure. Relapse usually occurs within 2 weeks of the original infection and is caused by the same pathogen. Selection of antibiotics for treatment of relapsed UTI should be guided by culture and susceptibility testing, and the duration of antibiotic therapy should be at least 2 weeks in length.	**Case 71-7 (Questions 1, 2)**
9	Recurrent UTI, which occurs >2 weeks after the original infection, is treated as a new infection with antibiotic considerations similar to those for the initial infection. Females with frequent infections (≥3/year) may be considered for chronic prophylaxis therapy. Females with identifiable causes of reinfection (eg, associated with sexual intercourse) may self-administer prophylactic antibiotics.	**Case 71-6 (Questions 4, 5, 7, 8), Tables 71-3, 71-4**
10	Asymptomatic bacteriuria (≥10^5 bacteria per milliliter of urine in the absence of clinical signs/symptoms of UTI) is particularly common in children, the elderly, pregnant females, and in patients with diabetes. Treatment of asymptomatic bacteriuria for prevention of subsequent infection and associated complications is routinely recommended in children and pregnant females. However, treatment of the elderly and patients with diabetes has not shown	**Case 71-7 (Questions 3, 4)** **Case 71-8 (Question 1)** **Case 71-9 (Question 1)**

	clear benefits and is not currently recommended.	
11	Prostatitis is a relatively common infection in males and is caused by bacteria similar to those causing uncomplicated UTI in females. Acute bacterial prostatitis is usually treated with either a fluoroquinolone or TMP-SMX for a period of 2–4 weeks. Chronic prostatitis persists in a small percentage of males after acute infection and is usually treated for 4–6 weeks, although longer courses may sometimes be required.	**Case 71-12 (Questions 1, 2)**

INTRODUCTION

Incidence, Prevalence, and Epidemiology

Urinary tract infection (UTI) is an acute or a chronic infection, usually bacterial in origin, that may affect any part of the upper or lower urinary system.

Infections of the bladder are referred to as *cystitis*, and infections involving the parenchyma of the kidneys are known as *pyelonephritis*. UTIs occur frequently in both community and hospital environments and are the most common bacterial infections in humans.[1–3] The term UTI encompasses a spectrum of clinical entities ranging in severity from asymptomatic infection to acute pyelonephritis with sepsis.[1–4] Approximately 8 to 9 million cases of acute cystitis and 250,000 cases of acute pyelonephritis occur annually in the United States, resulting in >100,000 hospitalizations.[2,5,6] Direct costs associated with the diagnosis and

treatment of UTI have been estimated at ~$3 billion annually in the United States.[3,6,7] UTI is predominantly a disease of females, with >50% of all females experiencing at least one infection during their lifetime.[2,5] The overall likelihood of developing a UTI is ~30 times greater in females than in males because of anatomic and physiologic differences.[3,7,8] The female urethra is relatively short and allows bacteria easy access to the bladder. In contrast, males are partly protected because the urethra is longer and antimicrobial substances are secreted by the prostate.[1,3,7,8]

Approximately 1% of boys and 3% to 5% of girls experience at least one UTI during childhood and 30% to 50% of these will have at least one recurrence.[9] The incidence of UTI in neonates is about 1% and is more frequent in male neonates, frequently because of congenital structural abnormalities.[10] UTIs in males also occur with increased frequency after age 50, when prostatic obstruction, urethral instrumentation, and surgery influence the infection rate. Infection in younger males is rare and requires careful evaluation for urinary tract pathology.[11,12]

Of females between the ages of 15 and 24 years, 1% to 5% have asymptomatic bacteriuria (ASB). This is defined as two consecutive voided urine specimens showing $\geq 10^5$ bacteria/milliliter (mL) of urine in females, or as a single clean-catch voided specimen in males without signs or symptoms of UTI. ASB prevalence increases 1% to 2% for each decade of life, and ~10% to 16% of females have ASB after age 70.[1,8,13,14] The prevalence of ASB in the elderly living at home is 5% to 20%, increasing to 20% to 50% in extended care facilities and 30% in hospitals.[3,13,15,16] The incidence of actual UTI also continues to rise with increasing age.[15,16] Reasons for higher ASB and UTI rates in elderly persons include the high prevalence of prostatic hypertrophy in males, incomplete bladder emptying caused by underlying diseases or medications, dementia, and urinary and fecal incontinence.[8,15–17] Whether ASB in older age is associated with decreased survival remains controversial[17,18]; however, the presence of ASB is associated with decreased functional ability of institutionalized persons,[13,15] and symptomatic UTI has been

independently associated with a threefold increased risk of vertebral fractures.[19]

Etiology

UNCOMPLICATED VERSUS COMPLICATED INFECTIONS

An important distinction in the characterization and treatment of UTI is that of uncomplicated versus complicated infections. Uncomplicated UTI, either cystitis or pyelonephritis, occurs in females who have normal structure and function of the genitourinary tract and who have no other factors that would put them at risk for more severe or complex infections.[3,5,20] By contrast, complicated infections are associated with conditions that increase the risk of acquiring infection, the potential for serious outcomes, or the risk of therapeutic failure. Such conditions include genitourinary tract abnormalities that may interfere with normal urine flow. Infections in males, children, and pregnant females, and those that are health care–associated in origin are automatically considered complicated. Other examples of complicated infections include those associated with structural and neurologic abnormalities of the urinary tract, metabolic or hormonal abnormalities, impaired host responses, instrumentation and catheterization of the urinary tract, and those caused by unusual pathogens (eg, yeasts, *Mycoplasma*).[3,5,20] Uncomplicated infections are always community acquired and are caused by the organisms typical to that etiology. Complicated UTI may be caused by pathogens associated with either community-acquired or health care–associated infections, depending on the source of bacterial acquisition and specific underlying patient risk factors. Complicated infections are also more often polymicrobial in etiology, associated with more antibiotic-resistant pathogens, and generally require a longer duration of therapy.

COMMUNITY-ACQUIRED INFECTIONS

Most UTIs are caused by gram-negative aerobic bacilli from the intestinal tract. *Escherichia coli* causes 75% to 95% of community-

acquired, uncomplicated UTIs.[1,3,20] Coagulase-negative staphylococci (eg, *Staphylococcus saprophyticus*) account for 5% to 20% of UTIs in younger females.[1,3,5] Other Enterobacterales (eg, *Proteus mirabilis*, *Klebsiella*) and *Enterococcus faecalis* also are common pathogens.[1,3,20] Uncomplicated infections are nearly always caused by a single pathogen.

HEALTH CARE–ASSOCIATED INFECTIONS

UTIs occur in up to 10% of hospitalized patients and represent 20% to 30% of all nosocomial infections.[21–23] *E. coli* remains the most common pathogen in hospital-acquired or other complicated UTI but is responsible for only 20% to 30% of these infections. Other gram-negative organisms, such as *Pseudomonas aeruginosa*, *Klebsiella*, *Proteus*, *Enterobacter*, and *Acinetobacter*, cause significantly more infections (up to 25%) compared to the community setting.[5,22,23] *Enterococcus* is also a common pathogen in hospital-acquired UTIs and accounts for ~15% of infections.[22,23] UTIs caused by *S. aureus* are usually the result of hematogenous spread but are also associated with urinary catheterization.[1,22–24] *Candida* is a common pathogen in hospital-acquired infections and may be involved in 20% to 30% of cases.[21–23] In contrast to the usually monomicrobial uncomplicated infections, UTIs associated with structural abnormalities or indwelling urinary catheters are often caused by multiple pathogens.[1,21–24]

Pathogenesis and Predisposing Factors

The spread of bacteria to the urinary tract typically occurs via the ascending route. A UTI usually begins with heavy and persistent colonization of the introitus (ie, vaginal vestibule and urethral mucosa) with intestinal bacteria. Colonization of the urethra then leads to retrograde infection of the bladder and the development of cystitis.[25,26]

The bladder has defense mechanisms that prevent spread of the infection after urethral colonization has occured.[1,3,22] Urination

effectively washes bacteria out of the bladder if the urine flows freely and the bladder is emptied completely. Substances in the urine, including organic acids (which contribute to low pH) and urea (which contributes to high osmolality), are antibacterial. The bladder mucosa also has antibacterial properties.[1,3,22] Other substances, including immunoglobulin A and glycoproteins (eg, Tamm–Horsfall protein), are actively secreted into the urine and prevent adherence of bacteria to uroendothelial cells.[22,25,26]

Focal renal involvement leading to pyelonephritis may result from the spread of bacteria via the ureters and may be facilitated by vesicoureteral reflux or decreased ureteral peristalsis. Ureteral peristalsis is decreased in pregnancy, by ureteral obstruction, or by gram-negative bacterial endotoxins.[1,25,26] Reflux can be produced by cystitis alone or by anatomic defects.

Bacterial virulence factors contributing to the development of UTI include expression of specific adhesin molecules, bacterial polysaccharides, and bacterial enzymes. Other factors predisposing to the development of UTI are dependent on the host and may include extremes of age, female sex, sexual activity, use of contraception, pregnancy, urinary tract instrumentation or catheterization, urinary tract obstruction, neurologic dysfunction, renal disease, previous antimicrobial use, and expression of A, B, and H blood group oligosaccharides on the surface of epithelial cells.[1–3,17,25,27]

The incidence of ASB in pregnant females is as high as 17%, which is approximately twice that of similarly aged nonpregnant females.[1,13,28,29] The incidence of acute symptomatic UTI, both cystitis and pyelonephritis, in pregnant females with untreated bacteriuria also is high and may reach 40%.[3] Many factors contribute to the increased susceptibility of the pregnant female to colonization and infection; these include hormonal changes, anatomic changes, progressive urinary stasis, and glucose in the urine.[28,29] Hormonal changes have also been linked to a significantly higher risk of UTI in menopausal females.[3] Estrogen promotes an acidic vaginal pH and proliferation of normal flora such as *Lactobacillus*, both factors that reduce pathogenic colonization of the vagina. Likewise, reduction of

estrogen production during menopause allows significant colonization of the vaginal tract with *E. coli* and other enteric bacilli, thus predisposing to subsequent infection.[3]

Renal disease increases the susceptibility of the kidney to infection.[1] The incidence of UTI among renal transplant recipients ranges from 35% to 80% without prophylactic antibiotic therapy.[30] Patients with spinal cord injuries, stroke, atherosclerosis, or diabetes may have neurologic dysfunction that predisposes to UTI as a result of urinary retention and/or need for catheterization. Furthermore, prolonged immobilization facilitates hypercalciuria and stone formation in some of these patients.[1,5,25]

Prior antimicrobial use (within the previous 15–28 days) for UTI or other infections increases the relative risk of UTI in females threefold to sixfold.[3] The proposed mechanism for this is alteration of normal flora of the urogenital tract and subsequent colonization with pathogenic bacterial strains.[2,3]

Diabetes mellitus is associated with a higher risk factor for UTI because glucose in the urine is promoting bacterial growth and impairing leukocyte function. Anatomic, neurologic, and immunologic abnormalities of the urinary tract in patients with diabetes contribute to the risk of infection, often because of more frequent urinary tract instrumentation.[31,32] Several studies have documented a twofold to threefold increase in UTI in females with diabetes compared to those without; rates of relapses and reinfections, as well as complications such as pyelonephritis, are also higher.[31–33]

Studies have supported an association between sexual intercourse and UTI among otherwise healthy females.[2,3,25,34] Specific contraceptive practices, particularly the use of spermicides, and the use of a diaphragm, cervical cap, or condom in combination with spermicidal jelly increases the risk of UTI compared with the use of the barrier method alone.[2,27,34] Diaphragm users are approximately three times more likely to experience a UTI than are females using other contraceptive methods, especially when the diaphragm is used in conjunction with spermicidal jelly.[2,27] The exact mechanisms of infection related to sexual intercourse and contraceptive methods are unclear but appear to be related to

alterations in vaginal flora allowing for bacterial overgrowth and subsequent infection.[1–3]

URINARY CATHETERS

Instrumentation or catheterization of the urinary tract is an important predisposing factor for health care–associated UTI. Catheter-associated urinary tract infection (CAUTI) occurs in up to 30% of patients who have been catheterized and is the most common type of hospital-acquired infection.[23] CAUTIs also are major causes of nosocomial gram-negative bacteremia.[21,23] Other urologic procedures, such as cystoscopy, transurethral surgery, prostate biopsy, and upper urinary tract endoscopy, are much less likely to result in infection, unless there is preexisting bacteriuria or bacterial colonization in other sites (eg, prostate, renal stones). Any obstruction to the free flow of urine (eg, urethral stenosis, stones, tumor) or mechanical difficulty in evacuating the bladder (eg, prostatic hypertrophy, urethral stricture) also predisposes patients to UTI and potential complications such as sepsis.[1]

CAUTI can occur by bacterial entry from several routes. The urethral meatus and the distal third of the urethra normally are colonized by bacteria; therefore, initial catheter insertion can introduce bacteria into the bladder. Bacteria contaminating catheter junctions and the urine collection bag can migrate through the catheter lumen to the bladder, initiating infection.[23] The extraluminal space in the urethra also has been considered a potential route of contamination and subsequent infection. The risk of infection is directly related to the catheter insertion technique, care of the catheter, duration of catheterization, and the susceptibility of the patient. A diagnostic or single, short-term catheterization is associated with a much lower risk of infection than is indwelling, long-term catheterization.[23] Despite careful technique, the risk of contaminating a sterile bladder with urethral bacteria is always present; each reinsertion of the catheter also increases risk of infection.[23]

CAUTIs have been markedly reduced by the closed sterile drainage system, the most common type of catheter currently in use, in which the drainage tube leads from the catheter directly to a closed plastic collection bag. The overall incidence of infection with the closed system using careful insertion and maintenance is about 20%; the risk increases to 50% after 14 days of catheterization.[23] Condom catheters are associated with a lower incidence of bacteriuria than are indwelling urethral catheters. These catheters avoid problems associated with insertion of a tube directly into the urinary tract; nevertheless, urine within the catheters may have high concentrations of organisms so that colonization of the urethra and subsequent cystitis may still develop.[23]

Application of antibacterial substances to the collection bag or exterior surface of the drainage tube does not decrease the incidence of bacteriuria.[23,35,36] The use of antimicrobial-impregnated catheters (eg, silver, rifampin plus minocycline) may decrease rates of bacteriuria and UTI.[23,35,36] The overall effects of antibiotic-impregnated catheters on infection rates, patient outcomes, and antibiotic resistance are not known, however, and their routine use is not currently recommended.[23,35]

Clinical Presentation

Symptoms commonly associated with lower tract UTI (eg, cystitis) include burning on urination (dysuria), frequent urination, suprapubic pain, and blood in the urine (hematuria). Patients with upper tract infection (eg, pyelonephritis) may also present with loin pain, costovertebral angle (CVA) tenderness, fever, chills, nausea, and vomiting.[1–5,37]

Clinical signs and symptoms correlate poorly with either the presence or the extent of the infection. Symptoms common to lower UTI often are the only positive findings in upper UTI (ie, subclinical pyelonephritis).[1,4] The probability of true infection in females who present with one or more symptoms of UTI is only about 50%.[38] The presence of dysuria, back pain, pyuria, hematuria, bacteriuria, and a

history of previous UTI may enhance the probability of true infection; the absence of dysuria or back pain, and history of vaginal discharge or irritation significantly decrease the likelihood of bacterial infection.[38],[39] The combination of dysuria plus urgency or frequency in the absence of vaginal discharge or irritation increases the probability of true infection to >90%.[38],[39] Fever, chills, flank and back pain, nausea and vomiting, or CVA tenderness are highly suggestive of acute pyelonephritis rather than of cystitis.[4],[5],[37] Many elderly patients with UTI are asymptomatic without pyuria. Likewise, nonspecific symptoms such as failure to thrive and fever may be the only manifestations of UTI in neonates and children younger than age 2 years.[1]

Diagnosis

Diagnosis of UTI based on clinical findings alone is accurate in only ~70% of patients.[38],[39] Urinalysis (UA) is a series of laboratory tests commonly performed in patients suspected of having a UTI. In combination with appropriate clinical findings, the UA effectively improves the overall diagnostic accuracy for UTI.[38],[39] Macroscopic analysis using a rapid “dipstick” method describes the color of the urine; measures its specific gravity; and estimates the pH, glucose, protein, ketone, blood, and bilirubin contents as well as presence of leukocytes and nitrite (see subsequent text). Microscopic analysis of urine sediment, obtained by centrifugation, determines the presence and quantity of leukocytes, erythrocytes, epithelial cells, crystals, casts, and bacteria. In patients with UTI, microscopic examination of urine sediment reveals many bacteria (usually >20 per high-power field [HPF]). Gram staining of uncentrifuged (“unspun”) urine shows at least one organism per immersion oil field and usually correlates with a positive urine culture result. Pyuria (ie, eight or more white blood cells [WBC] per milliliter of unspun urine or two to five WBC/HPF of centrifuged urine) is frequently seen in patients with UTI. WBC casts in the urine strongly suggest acute pyelonephritis.[1],[38],[39]

Rapid diagnostic dipstick tests are widely available and easily performed. The nitrite test detects nitrite formation from the reduction of nitrates by bacteria. Although a positive nitrite reading is useful, false-negative results do occur.[38],[39] The leukocyte esterase test detects the esterase activity of activated leukocytes in the urine. A positive test result correlates well with significant pyuria[40]; however, both false-negative and false-positive findings can occur with the leukocyte esterase test as well.[38] Nitrite and leukocyte esterase tests are useful in ruling out the presence of infection if results of both tests are negative, whereas positive results of both tests in combination are highly suggestive of the presence of infection.[38]

The gold standard criterion for the diagnosis of UTI is the urine culture with a positive UA finding.[1–3,37,38] Proper interpretation of these cultures depends, however, on appropriate urine collection techniques. Urinating into a sterile collection cup using the midstream clean-catch technique is the most practical method of urine collection. This method of urine specimen collection is especially useful for male patients, but it is less useful in female patients because bacterial contamination is extremely difficult to avoid.[1] The external urethral area must first be thoroughly cleaned and rinsed, then the urine specimen must be collected after initiation of the urine stream (hence “midstream”).

Urinary catheterization for a urine culture sample yields reliable results if performed carefully. Suprapubic bladder aspiration generally is not painful and is quite reliable. It is not practical for routine office or clinic practice, but it may be useful when voided urine samples yield questionable results or when patients have voiding problems. Because contamination is negligible, any number of bacteria found by this method reflects infection.[1–3]

Urine must be plated on culture media within 20 minutes of collection to avoid erroneously high colony counts from bacterial growth in urine at room temperature. Otherwise, urine should be promptly refrigerated until it can be cultured. Colony counts are also affected by the concentration of bladder urine; bacterial counts are higher in first-voided morning urine samples compared with those obtained from the same patient later in the day.[1],[37],[38]

Greater than 10^5 colonies of bacteria per mL cultured from a midstream urine specimen confirms a UTI. A single, carefully collected urine specimen provides 80% reliability, and two consecutive cultures of the same organism are virtually diagnostic.[1–3] However, the classic definition of UTI as $\geq 10^5$ bacteria/mL is inaccurate in diagnosing patients with true UTI. Approximately 30% to 50% of patients with acute cystitis have $<10^5$ bacteria/mL.[5,13] In a symptomatic patient, using a definition of $\geq 10^2$ bacteria/mL is more accurate and avoids failure to diagnose infection in many patients.[5]

Diagnosis of UTI in males also requires different interpretation of laboratory data. Contamination of urinary specimens is much less likely to occur in males compared with females, and numbers of bacterial colonies in specimens are therefore much lower. Greater than 10^3 bacteria/mL is thus highly suggestive of UTI in males.[11,12,38] In addition, although a positive nitrite test result in a symptomatic male is highly indicative of the presence of an acute UTI, a negative nitrite test result does not necessarily exclude infection, and a urine culture should be performed.[38,41]

Diagnosis of UTI in children is particularly problematic because of the difficulties and high contamination rates associated with commonly used methods of urine specimen collection. Suprapubic aspiration is the most accurate method in children, followed by urinary bladder catheterization.[3,37] Although clean-catch and bag methods (ie, collecting urine into a bag placed around the urogenital area) are susceptible to contamination and inaccurate results, they are also the most preferred methods for parents and health care personnel because they are simple and noninvasive. The choice of diagnostic tests for children will therefore vary based on the experience, skill, and preferences of those involved with the child.[37]

Simplified culture methods are as reliable as traditional laboratory methods for bacterial identification and quantification. The dip-slide (eg, Uricult®) and pad-culture (Microstix®) methods are accurate, differentiate between gram-positive and gram-negative organisms, and are similar in cost. The dip-slide method has the added advantages of ease of storage and a nitrite indicator pad.

Overview of Drug Therapy

The cornerstone of effective treatment of UTI is the appropriate selection and use of antibiotics. Antibiotic treatment of UTI is well studied and antibiotic choice and duration of therapy for acute, uncomplicated infections are reasonably clear. Consensus guidelines from the Infectious Diseases Society of America (IDSA) and the European Society for Microbiology and Infectious Diseases (ESMID) recommend a 5-day course of nitrofurantoin, 3 days of trimethoprim–sulfamethoxazole (TMP-SMX), or a single dose of fosfomycin trometamol as first-line antibiotic treatment of acute uncomplicated cystitis in females.[20] Nitrofurantoin and TMP-SMX are familiar agents, whereas fosfomycin is a lesser known antibiotic that has made a resurgence in clinical use because of low rates of resistance among common uropathogens.[20,42]

Fluoroquinolones and β-lactam antibiotics, such as amoxicillin–clavulanate and various cephalosporins, are recommended by the IDSA/ESMID guidelines as alternative agents for treating acute uncomplicated cystitis.[20] The recommended durations of therapy for fluoroquinolones and β-lactams are 3 days and 3 to 7 days, respectively. Fluoroquinolones, cephalosporins, aminoglycosides, TMP-SMX, extended-spectrum penicillins (ie, piperacillin–tazobactam), or a carbapenem are recommended by the IDSA/ESMID for the treatment of acute pyelonephritis in females.[20] The choice of a specific agent for pyelonephritis depends primarily on whether the patient is hospitalized or treated as an outpatient, local susceptibility patterns, and whether therapy is empiric or based on known susceptibilities. The duration of therapy for acute pyelonephritis ranges from 5 to 14 days and is dependent on which specific antibiotic is being used.[20] Parameters for monitoring response to treatment of either uncomplicated cystitis or pyelonephritis are primarily resolution of clinical signs and symptoms; repeat urinary cultures are not usually required. Patients with complicated UTI or recurrent infections may require additional monitoring and long-term follow-up, and antibiotic selection must be guided by culture and susceptibility (C&S) testing. Patient monitoring

related to the safety and tolerability of antibiotic therapy is required regardless of type of infection, as is effective patient counseling.

LOWER URINARY TRACT INFECTION

Initial Patient Evaluation and Determining Goals of Therapy

CASE 71-1

QUESTION 1: V.Q., a 20-year-old female with no previous history of UTI, reports burning on urination, frequent urination of a small amount, and bladder pain. She has no fever or CVA tenderness. A clean-catch midstream urine sample shows gram-negative rods on Gram stain. A urine sample for C&S testing is ordered, and the results of a UA are as follows:

Appearance, straw-colored (normal, straw)
Specific gravity, 1.015 (normal, 1.002–1.028)
pH, 8.0 (normal, 5.5–7.0)
Protein, glucose, ketones, bilirubin, and blood, all negative (normal, all negative)
WBC, 10 to 15 cells/low-power field (LPF; normal, 0–2 cells/LPF)
Red blood cells (RBCs), 0 to 1 cells/LPF (normal, 0–2 cells/LPF)
Bacteria, many (normal, 0 to rare)
Epithelial cells, 3 to 5 cells/LPF (normal, 0 to few cells/LPF)
Based on these findings, V.Q. is presumed to have a lower UTI.

What should be the goals of therapy of V.Q.'s infection at this time? What factors should be considered before selecting an antibiotic for V.Q.?

The goals of therapy for treatment of acute cystitis are to effectively eradicate the infection and prevent associated complications, while minimizing adverse effects and costs associated with drug therapy. Selection of a specific antimicrobial agent should be made after considering several factors: (a) most likely pathogens, (b) resistance rates within the specific geographic area, (c) desired duration of therapy, (d) clinical efficacy and toxicity profiles of various agents, (e) cost and availability of specific agents,

and (f) patient characteristics such as allergies, compliance history, and underlying comorbidities.[20] Because resistance rates among various pathogens vary considerably among geographic areas, clinicians must be familiar with those prevalent within their specific practice area.[20,43,44]

Drug treatment of a lower UTI often is started empirically or before C&S results are known because the most probable infecting organisms and their susceptibility to antibiotics can be predicted reasonably well (**Table 71-1**). Approximately 75% to 95% of community-acquired infections are caused by Enterobacterales, particularly *E. coli*. Although these organisms may be sensitive to ampicillin, amoxicillin, and the sulfonamides (such as TMP-SMX), resistance to these agents is common.[43–47] Ampicillin resistance occurs in 25% to 70% of community-acquired isolates[43–47]; overall resistance in the United States is currently 30% to 50%. Ampicillin and amoxicillin are therefore not recommended as first-line empiric agents for UTI.[1,5,20,43–47] TMP-SMX has been an agent of choice for many years; however, TMP-SMX resistance has significantly increased in recent years and may be 20% to 45% among community-acquired *E. coli* isolates in some geographic areas.[20,43–47] Although traditionally associated with hospital-acquired infections, *E. coli* and *Klebsiella* resistance, caused by production of ESBL enzymes that confer resistance to penicillins and cephalosporins, has also been steadily increasing among community-acquired pathogens.[48,49] Another relatively common organism is *S. saprophyticus.* Most strains are susceptible to sulfonamides, TMP-SMX, penicillins, and cephalosporins. Commonly used medications and doses are shown in **Table 71-2**.

Table 71-1

Overview of Treatment of Urinary Tract Infections

Common Uropathogens	Antibacterial of Choice
Uncomplicated Urinary Tract Infection	
Escherichia coli	TMP-SMX[a]

Proteus mirabilis	TMP-SMX[a]
Klebsiella pneumoniae	TMP-SMX[a]
Enterococcus faecalis	Ampicillin, amoxicillin
Staphylococcus saprophyticus	First-generation cephalosporin or TMP-SMX
Complicated Urinary Tract Infection[b,c]	
E. coli	First-, second-, or third-generation cephalosporin; TMP-SMX[c]
P. mirabilis	First-, second-, or third-generation cephalosporin
K. pneumoniae	First-generation cephalosporin; fluoroquinolone
ESBL-producing organisms[d]	Nitrofurantoin, fosfomycin, carbapenem, amikacin, ceftolozane–tazobactam, ceftazidime–avibactam
Enterococcus faecalis	Ampicillin or vancomycin ± aminoglycoside
Pseudomonas aeruginosa	Antipseudomonal penicillin ± aminoglycoside; ceftazidime; cefepime; fluoroquinolone; carbapenem[e]
Enterobacter	Fluoroquinolone; TMP-SMX; carbapenem
Indole-positive Proteus	Third-generation cephalosporin; fluoroquinolone
Serratia	Third-generation cephalosporin; fluoroquinolone
Acinetobacter	Carbapenem; TMP-SMX
Staphylococcus aureus	Penicillinase-resistant penicillin; first-generation cephalosporin; vancomycin

ESBL, extended-spectrum β-lactamase; TMP-SMX, trimethoprim–sulfamethoxazole.

[a]Caution in communities with increased resistance (>10%–20%).

[b]Drug selection based on culture and susceptibility testing when possible.

[c]Oral therapy when appropriate. Nitrofurantoin, fosfomycin, fluoroquinolones, or cephalosporins should be used in areas with increased TMP-SMX resistance.

[d]Choice of specific antibiotic should be guided by susceptibility reports.

[e]Ertapenem has no activity against *Pseudomonas*.

Table 71-2
Commonly Used Oral Antimicrobial Agents for Acute Urinary Tract Infections

Drug	Usual Dose[a]		Pregnancy[b]	Breast Milk[b]	Comments[c]
	Adult	Pediatric			Pediatric
Amoxicillin	500 mg every 8 or 12 hours or 3 g single dose	20–40 mg/kg/day in three doses	Crosses placenta (cord) = 30% (maternal)[d]	Small amount present	High resistance rates, not for empiric use
Amoxicillin/ potassium clavulanate	500/125 mg every 12 hours	20–40 mg/kg/day (amoxicillin content) in three doses	Unknown	Unknown	
Cephalexin	250–500 mg every 6 hours	25–50 mg/kg/day in two to four doses	Crosses placenta	Enters breast milk	Cephalosporins are alternative choices for patients allergic to penicillins, although cross-hypersensitivity can occur. May be associated with higher failure rates compared to other drug classes
Cefaclor	250–500 mg every 8 hours	20–40 mg/kg/day in two to three doses	Crosses placenta	Small amount present	
Cefpodoxime proxetil	100 mg every 12 hours	10 mg/kg/day in two doses	Crosses placenta	Variable amounts; milk = 0%–16% of serum	
Cefdinir	300 mg every 12 hours (or 600 mg every 24 hours)	14 mg/kg/day in one or two doses	Crosses placenta	Not detectable after single 600-mg dose	
Norfloxacin[e]	400 mg every 12 hours	Avoid	Arthropathy in immature animals	Unknown	Avoid concomitant administration of antacids, divalent and trivalent cations, and sucralfate[f]
Ciprofloxacin[e]	250–500 mg every 12 hours Extended release: 500 mg to 1 g every 24 hours	Avoid	Arthropathy in immature animals	Unknown	Alternative choice for patients allergic to β-lactams.[f] Useful for pseudomonal infection. *Caution with concomitant use of QTc-prolonging agents.*
Levofloxacin	250 or 750 mg every 24 hours	Avoid	Arthropathy in immature animals	Milk = 100% of serum[d]	*Caution with concomitant use of QTc-prolonging agents.*
Nitrofurantoin	100 mg every 12 hours (eg, Macrobid®) 50–100 mg every 6 hours (eg, Macrodantin®)	5–7 mg/kg/day in four doses (eg, Macrodantin®)	Hemolytic anemia in newborn	Variable, but up to 30%; may cause hemolysis in G6PD-deficient baby	Alternative choice *To be taken with food or milk. May cause brown or rust-yellow discoloration of urine.*
Trimethoprim (TMP)	100 mg every 12 hours	4–6 mg/kg/day in two doses	Crosses placenta (cord) = 60%; (maternal) folate antagonism, avoid during first trimester; teratogenic in rats	Milk > serum[d]	Alternative choice

Drug	Usual Dose[a]		Pregnancy[b]	Breast Milk[b]	Comments[c]
	Adult	Pediatric			Pediatric
TMP-SMX	160–800 mg every 12 hours	10 (6–12) mg/kg/day (TMP component in two doses)	SMX crosses placenta (cord) = 60%; maternal folate antagonism, avoid during first trimester; displacement of bilirubin may lead to hyperbilirubinemia and kernicterus in newborn; avoid after 32 weeks of gestation; teratogenic in some animal studies.	SMX enters breast milk in concentrations greater than serum; displacement of bilirubin may lead to neonatal jaundice; may cause hemolysis in G6PD-deficient baby.	*To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.* Monitor HIV-infected patients closely for development of adverse hematologic reactions. First-line agent for prostatitis
Fosfomycin	3-g single dose	2-g single dose (children <12 years)	Crosses placenta	Present in breast milk	Recommended option for uncomplicated cystitis

G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; TMP-SMX, trimethoprim–sulfamethoxazole.

[a]Where dosing ranges are provided, lower doses are often used for uncomplicated infections and higher doses reserved for complicated infections.

[b]Also see Chapter 49, Obstetric Drug Therapy.

[c]Includes unique patient consultation information in italics.

[d]Denotes drug concentration.

[e]May increase theophylline and warfarin concentrations when given concurrently. Carefully monitor theophylline serum concentrations and international normalized ratio (INR) during quinolone use.

[f]Same comments apply to all fluoroquinolones.

ROLE OF URINE CULTURES

Case 71-1, Question 2: Is it necessary to order a pretreatment urine C&S test for V.Q.?

Many investigators question the value of pretreatment urine cultures for acute uncomplicated UTI.[1,2,5,20] Females with lower UTI usually have pyuria on UA and respond rapidly to appropriate antimicrobial treatment. Pyuria may be a better predictor of treatable infection than the colony count obtained on urine culture. Furthermore, the urine culture accounts for a large portion of the cost of treating a patient with a UTI.[50] Consequently, in patients such as V.Q. with uncomplicated, acute, lower UTI, it is more cost-effective to order a UA and, if pyuria is present on UA, to forego a urine culture and empirically start a conventional course of antibiotic therapy. If V.Q. remains symptomatic 48 hours later, a C&S test can then be ordered. Considerations are different in patients with complicated infections. In complicated UTI, predisposing factors that lead to infection and history of frequent previous antibiotic use make both causative pathogens and associated antibiotic susceptibilities much less predictable. Use of C&S testing is therefore commonly recommended for treatment of complicated UTI to guide appropriate antibiotics.[1–3,5,20]

INITIAL ANTIBIOTIC SELECTION

Case 71-1, Question 3: What antibiotics may be appropriate for treatment of V.Q.'s infection?

IDSA/ESMID guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis were published in 2011 and serve as the basis for antibiotic selection in V.Q.[20] (**Table 71-3**). The recommended first-line agents for treatment of this patient's uncomplicated cystitis include TMP-SMX, nitrofurantoin, and

fosfomycin trometamol; a fourth recommended antibiotic, pivmecillinam, is not commercially available in the United States.

Table 71-3

Summary of Evidence-Based Recommendations for Treatment of Acute Uncomplicated Cystitis and Pyelonephritis

Recommendations	Recommendation Grades[a]
Cystitis	
Preferred Agents	
Nitrofurantoin monohydrate/macrocrystals 100 mg PO twice daily × 5 days	A-1
TMP-SMX 160/800 mg (1 double-strength tablet) PO twice daily × 3 days	A-1
Trimethoprim 100 mg PO twice daily × 3 days is considered equivalent to TMP-SMX and is the preferred agent in some regions.	A-3
Fosfomycin trometamol 3 g PO × 1 dose	A-1, but appears to have inferior microbiologic efficacy compared with standard short-course therapies with agents such as trimethoprim or nitrofurantoin
Pivmecillinam 400 mg PO twice daily × 3–7 days (not commercially available in the United States)	A-1, but may have inferior efficacy compared with other available therapies
Resistance Considerations	
A specific antibiotic is no longer recommended for empirical treatment when the prevalence of resistance is ≥20%.	B-3 for TMP-SMX No recommendation for other agents
Alternative agents	
Fluoroquinolones	
Fluoroquinolones (ciprofloxacin or levofloxacin) PO × 3 days are highly efficacious for acute cystitis.	A-1

Recommendations	Recommendation Grades[a]
Fluoroquinolones should be reserved for other important clinical uses because of propensity for collateral damage.	A-3
β-*Lactams*	
β-Lactams (including amoxicillin–clavulanate, cefdinir, cefaclor, and cefpodoxime– proxetil) PO × 3–7 days are appropriate when other recommended agents cannot be used.	B-1
Other β-lactams such as cephalexin are less well studied but may also be appropriate in certain settings.	B-3
β-Lactams generally have inferior efficacy and more adverse effects compared with other antimicrobials for UTI.	B-1
Pyelonephritis	
All Patients	
Urine culture and susceptibility testing should be performed, and initial empirical antibiotic therapy tailored appropriately based on results.	A-3
Outpatient Treatment	
Fluoroquinolones	
Ciprofloxacin 500 mg PO twice daily × 7 days, ± an initial IV dose of ciprofloxacin 400 mg, a long-acting parenteral cephalosporin (eg, ceftriaxone 1 g) or a consolidated 24-hour dose of an aminoglycoside (eg, gentamicin 5–7 mg/kg)	A-1
Ciprofloxacin 1000 mg extended-release tablet PO once daily × 7 days, or levofloxacin 750 mg PO once daily × 5 days	B-2
If the local prevalence of fluoroquinolone resistance among uropathogens is >10%, an initial one-time IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered.	B-3
Alternative agents	

Recommendations	Recommendation Grades[a]
TMP-SMX 160/800 mg (1 double-strength tablet) PO twice daily × 14 days	A-1
If TMP-SMX susceptibility is not known, an initial IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered.	B-2 for a cephalosporin B-3 for an aminoglycoside
Oral β-lactams × 10–14 days are less effective than are other available agents.	B-3
If an oral β-lactam is used, an initial IV dose of a long-acting parenteral cephalosporin or a consolidated 24-hour dose of an aminoglycoside should be administered.	B-2 for a cephalosporin B-3 for an aminoglycoside
Hospitalized Patients	
One of the following antibiotic options may be used initially, based on local resistance data and on susceptibility results: IV fluoroquinolone; IV aminoglycoside ± IV ampicillin; extended-spectrum IV cephalosporin or extended-spectrum IV penicillin ± aminoglycoside; or IV carbapenem.	B-3

Quality of evidence: 1 = evidence from ≥1 properly randomized controlled trial; 2 = evidence from ≥1 well-designed clinical trial without randomization, from cohort or case–control analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

IV, intravenous; PO, orally; TMP-SMX, trimethoprim–sulfamethoxazole; UTI, urinary tract infection.

[a]Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation for or against use, respectively.

Source: Gupta K, Hooton TM, Naber KG, et al. International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Diseases Society of America and the European Society for Microbiology and Infectious Diseases. *Clin Infect Dis.* 2011;52:e103–e120.

TMP-SMX is effective as therapy for uncomplicated cystitis.[1–3,20,51] Gram-positive and gram-negative uropathogens, with the notable

exceptions of *Enterococcus* and *P. aeruginosa*, are generally susceptible to TMP-SMX.[20],[52] Although TMP-SMX may appear active against enterococci in vitro, clinical efficacy against this pathogen does not always correlate well and is variable. Furthermore, this combination is almost uniformly successful in the treatment of uncomplicated UTI, even against organisms that are resistant to either agent alone. Although resistance to trimethoprim has increased,[20],[43–48] resistance rates remain relatively low in some geographic areas and trimethoprim alone may be effective in managing UTI in many patients.

The ratio of trimethoprim to sulfamethoxazole in the available tablet products is 1:5 (eg, 80 mg trimethoprim and 400 mg sulfamethoxazole). This combination will achieve peak serum concentrations of the two drugs that approximate a 1:20 ratio. This ratio is optimal for synergistic activity against most microorganisms, although the drugs remain synergistic and bactericidal in ratios ranging from 1:5 to 1:40 in vitro.[52] Urinary concentrations of trimethoprim and sulfamethoxazole far exceed the minimum inhibitory concentrations (MIC) for most susceptible urinary pathogens. Therefore, good in vitro activity, excellent clinical success against susceptible strains (similar to that of the fluoroquinolones and other alternative agents), relatively low resistance rates among common pathogens, and low cost make TMP-SMX a reasonable choice in V.Q.[20] The 2011 IDSA/ESMID guidelines recommend TMP-SMX as an appropriate initial agent of choice in the treatment of acute, uncomplicated lower UTI in geographic areas where the incidence of TMP-SMX resistance among *E. coli* is <20%.[20]

Nitrofurantoin is also recommended as an appropriate agent for empirical treatment of acute uncomplicated cystitis.[20] Nitrofurantoin is almost completely absorbed after oral administration, but it barely reaches detectable levels in the plasma because it is rapidly eliminated (half-life, 20–60 minutes) into the urine and bile; the resulting high urine levels of 50 to 250 mg/L are well in excess of the MIC for most common pathogens causing UTI.[53],[54] Food substantially decreases the rate of absorption, but it increases the total bioavailability of nitrofurantoin by about 40%. This effect

lengthens the duration of therapeutic urine concentrations by about 2 hours.[53,54]

Nitrofurantoin's spectrum of activity includes *E. coli*, some *Pseudomonas* strains, *S. saprophyticus*, streptococci, and enterococci, whereas *Proteus*, *Enterobacter*, and *Klebsiella* are more likely to be resistant (susceptibility <60%).[20,54] Nitrofurantoin does not significantly alter the fecal or introital flora, and the development of resistance in previously sensitive strains does not often occur.[20,53,54] In contrast to ampicillin, TMP-SMX, and other drugs with relatively high resistance rates, nitrofurantoin has maintained excellent activity against most uropathogens; susceptibility rates among *E. coli* range from 90% to 99% in most geographic areas.[20,43–47,54] Nitrofurantoin has shown effectiveness similar to that of TMP-SMX, fluoroquinolones, or fosfomycin in the treatment of acute uncomplicated cystitis, and thus is recommended in the most recent clinical guidelines as an appropriate choice for treatment of uncomplicated UTI in patients such as V.Q. (Table 71-3).[20]

Fosfomycin trometamol has been successfully used for the treatment of UTI in many parts of the world for a number of years.[20,42] Fosfomycin is a phosphonic acid derivative that irreversibly blocks bacterial cell wall synthesis through inhibition of early cytoplasmic stages of peptidoglycan synthesis.[42,53] It has bactericidal activity against a broad range of gram-negative and gram-positive organisms including *E. coli* and other Enterobacterales, *P. aeruginosa*, and *Enterococcus.* Fosfomycin is also useful against methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug-resistant (MDR) pathogens including vancomycin-resistant enterococci (VRE), and extended spectrum β-lactamase (ESBL)-producing gram-negative bacteria that are becoming more common in certain practice settings.[20,42] Fosfomycin is ~40% absorbed after oral administration (granules marketed in a sachet form are dissolved in cold water) and is rapidly and almost completely excreted unchanged in the urine. Fosfomycin achieves mean urinary concentrations >500 mg/L within 6 to 8 hours of administration and maintains concentrations >100 mg/L for >24 hours after a single oral dose.[42,53] Single 3-g oral doses of

fosfomycin are clinically as effective as trimethoprim and nitrofurantoin, although microbiological efficacy may be less.[20] Fosfomycin is currently recommended for treatment of acute uncomplicated cystitis in the 2011 IDSA/ESMID guidelines (Table 71-3), and is substantially more expensive than is either TMP-SMX or nitrofurantoin.[20]

Alternative agents for the treatment of UTI in V.Q. include the fluoroquinolones and various oral β-lactam antibiotics.[20] The fluoroquinolones remain highly effective in the treatment of UTI. However, increasing rates of resistance among common uropathogens, and the potential for significant collateral effects on normal flora leading to complications such as *Clostridioides difficile* infection have led to recent recommendations that the fluoroquinolones not be routinely used as preferred agents in the treatment of uncomplicated UTI such as that present in V.Q.[20] Further details regarding the use of fluoroquinolones for UTI are discussed in Case 71-2.

Amoxicillin–clavulanate and several oral cephalosporins have been studied for the treatment of uncomplicated UTI. β-Lactams are generally comparable to TMP-SMX, but less clinically or microbiologically effective than are the fluoroquinolones.[20] β-Lactams require longer durations of treatment (see Case 71-1, Question 4), which makes them less attractive from the standpoint of ensuring patient adherence and may also predispose them to higher rates of drug-related adverse effects.[20] These relatively broad-spectrum agents may be associated with more frequent emergence of bacterial resistance, including ESBL-producing gram-negative bacilli.[20] Thus, the β-lactam antibiotics (with the exception of pivmecillinam) are currently only recommended for empirical treatment of uncomplicated cystitis when none of the other agents previously discussed can be used (Table 71-3).[20] Ampicillin and amoxicillin are specifically discouraged for empirical treatment of UTI because of the high resistance rates previously noted.[20]

V.Q. could be appropriately treated with TMP-SMX, nitrofurantoin, or fosfomycin. She has no apparent patient characteristics that would favor the use of one agent over another. In this case, the most

important factor to consider would be local antibiotic susceptibilities among community-acquired uropathogens, particularly *E. coli.* Local costs and availability of the different options would also be important to consider in V.Q.

Note that the current IDSA/ESMID guidelines do not apply to the empirical selection of antibiotics for complicated UTI. Complicated infections are often associated with more difficult pathogens (eg, *P. aeruginosa*) and increased risk of antibiotic resistance; fluoroquinolones are therefore considered preferred agents for initial treatment of complicated UTI with subsequent antibiotic therapy guided by the results of C&S testing.[1–3,5,24]

DURATION OF ANTIBIOTIC THERAPY

Case 71-1, Question 4: V.Q. is started on TMP-SMX for treatment of her infection. What would be the preferred duration of antibiotic therapy for V.Q.?

Outpatients with acute, uncomplicated UTI can be treated successfully with a single dose, a 3- to 5-day course of therapy, or a 7- to 14-day course of oral medications; the latter is considered excessive for most patients with uncomplicated infections and is seldom used.[1–3,5,20,55] A 3- to 5-day antibiotic regimen is just as effective as a 10-day regimen in achieving clinical cures and eradicating uropathogens, although this is antibiotic class specific.[1–3,5,20,55] TMP-SMX is recommended as the preferred agent for 3-day treatment regimens; the fluoroquinolones may also be used in this shorter duration (Table 71-3).[20] A 5-day course of nitrofurantoin is as effective as a 3-day course of TMP-SMX for acute uncomplicated cystitis, and the 5-day treatment duration is currently recommended.[20,56] β-Lactam antibiotics are more appropriately reserved for treatment courses of 3 to 7 days.[5,20] Longer treatment courses are also used in cases of treatment failure after regimens of shorter duration, as well as in the treatment of complicated UTI where longer courses of therapy (7–14 days) are associated with higher clinical success rates and improved outcomes.[1–3,24]

Even a single dose of an antibiotic may be effective. Bacteria disappear from the urine within hours of antibacterial therapy being initiated.[20] This, coupled with the urinary bladder's ability to defend itself through micturition, acidification, and inherent antibacterial activity, gives theoretic support to the clinical evidence that a large single dose of an antibiotic can eradicate a UTI. Fosfomycin trometamol is a perfect example of this principle: very high urinary concentrations of this bactericidal agent are maintained for >24 hours after a single 3-g oral dose and contribute to the favorable clinical efficacy observed in comparative trials.[20,42,53]

Although not recommended in the current guidelines, single doses of antibiotics other than fosfomycin are also occasionally used in treating acute, lower UTI in young females.[5,8,20] Examples of regimens used are TMP-SMX (two or three double-strength tablets), trimethoprim 400 mg, amoxicillin–clavulanate 500 mg, amoxicillin 3 g, nitrofurantoin 200 mg, ciprofloxacin 500 mg, and norfloxacin 400 mg.[1,20] The advantages of single-dose treatment of UTI include improved compliance, reduced cost, proven efficacy in a defined population of patients (ie, young females with acute, uncomplicated lower UTI), minimal side effects, and a potentially decreased incidence of bacterial resistance associated with antibiotic overuse. However, several concerns also exist regarding single-dose therapy.[5,8,20] First, sample sizes in most comparative studies were relatively small. Consequently, it is difficult to determine whether differences in effectiveness or incidence of side effects between single-dose and multiple-dose therapy are clinically significant. Meta-analysis of studies comparing single-dose versus longer regimens of TMP-SMX has demonstrated that single-dose therapy is significantly less effective in eradicating bacteriuria than are regimens of ≥5 days (83% vs 93%, respectively, $P > .001$) or ≥7 days in duration (87% vs 94%, respectively; $P = .014$).[20,51,55] Although fewer studies have directly compared single-dose versus 3-day therapies, numerous studies have shown that 3-day courses are as effective as courses of longer duration.[20,55] As discussed in Case 71-1, Question 3, reduced microbiologic efficacy was also observed with single-dose fosfomycin[20] and single-dose therapies have been associated with

higher rates of recurrence compared with therapies of longer duration.[5] A 3- or 5-day course of therapy is therefore currently recommended by the IDSA/ESMID for uncomplicated cystitis; a large single dose of fosfomycin is the sole single-dose regimen endorsed by the guidelines.[20]

Female patients with history or clinical presentation suggestive of complicated infection (eg, systemic manifestations of infection, renal disease, anatomic abnormalities of the urinary tract, diabetes mellitus, pregnancy), a history of antibiotic resistance, or a history of relapse after single-dose therapy should not receive single-dose regimens. Single-dose therapy is also not appropriate for male patients with UTI. Because V.Q. does not have any of these contraindications, she could theoretically receive single-dose therapy with an appropriate agent. Based on the preceding information, and according to current guidelines, a 3-day course of TMP-SMX, a 5-day course of nitrofurantoin, or a single dose of fosfomycin would be most appropriate for treatment of V.Q.'s infection (Table 71-3).[20]

When using short-course regimens, it is important to counsel the patient that the clinical signs and symptoms of infection may often not be completely resolved for 2 to 3 days after initiation of therapy. Therefore, symptoms that persist for a short while after beginning therapy (or actually completing therapy, in the case of single-dose regimens) are not necessarily indicative of treatment failure.

PHENAZOPYRIDINE

Case 71-1, Question 5: Along with TMP-SMX, phenazopyridine is also prescribed because of V.Q.'s reports of significant dysuria. Is phenazopyridine appropriate for this patient?

Phenazopyridine, a urinary tract analgesic, may occasionally be administered together with an antibacterial agent for the symptomatic relief of dysuria. Although phenazopyridine at a dose of 200 mg orally three times a day may relieve dysuria, it is ineffective in the actual eradication of true UTI. Phenazopyridine plus an

antibiotic is not any better than an antibiotic alone in terms of treatment efficacy; therefore, the drug is not likely of significant value in V.Q. and should not be routinely recommended. However, although most patients have resolution of symptoms within 24 to 48 hours of beginning therapy, certain patients with severe dysuria or delayed response to antibiotic therapy may benefit symptomatically from a short trial (1–2 days) of phenazopyridine.[5] The need for, and duration of, analgesic therapy must be individualized.

Phenazopyridine is an azo dye and may discolor the urine to an orange–red, orange–brown, or red color that can stain clothes. Other adverse effects of phenazopyridine occur after acute overdose, or as a result of accumulation in older patients or in patients with decreased renal function who take the drug chronically. In vivo, about 50% of phenazopyridine is metabolized to aniline, which can cause methemoglobinemia and hemolytic anemia. Hemolytic anemia associated with phenazopyridine occurs primarily in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.[57] Cases of reversible acute renal failure and allergic hepatitis have also been rarely reported after brief exposure to phenazopyridine.[57]

INTERPRETATION OF URINE CULTURE AND SUSCEPTIBILITY TEST RESULTS

Case 71-1, Question 6: Two days after V.Q. begins treatment for her infection with TMP-SMX, results of the C&S studies become available and reveal $>10^5$ bacteria/mL of *P. mirabilis*, which is susceptible to ampicillin, amoxicillin–clavulanate, cephalosporins, and gentamicin. The *Proteus* is intermediately susceptible to nitrofurantoin, and resistant to TMP-SMX and ciprofloxacin. V.Q. reports that she is symptomatically better since starting antibiotic therapy and that her dysuria and bladder pain are now almost completely resolved. How should these test results be interpreted? Is a change in V.Q.'s antibiotic therapy necessary?

Most females with either lower or upper UTI have $>10^5$ bacterial colonies/mL of urine. However, a major revision in the diagnostic criteria for symptomatic UTI has been the abandonment of the absolute requirement for growth of $\geq 10^5$ bacterial colonies/mL of

urine. The criterion of ≥100 bacteria/mL results in excellent sensitivity and specificity in correctly diagnosing and treating females with symptomatic infection.[13] This same criterion should also be applied to lower UTI when *S. saprophyticus* is isolated, because UTIs caused by this pathogen often are associated with low urine bacterial colony counts, suboptimal growth on commonly used media, and negative findings on nitrite screening.

Mixed flora (more than two organisms) is unusual in uncomplicated cystitis except in severely debilitated persons and other complicated infections. Thus, mixed flora in the setting of uncomplicated infection frequently suggests contamination, and a repeat specimen should be obtained.

Bacterial susceptibility to different antimicrobial drugs is usually determined by referencing interpretive criteria that correlate with achievable serum concentrations of those drugs. However, drugs useful in the treatment of UTI are excreted primarily by the kidney, and urine concentrations of these drugs may be 20 to 100 times greater than are serum concentrations. Therefore, infections caused by organisms that are only intermediately susceptible, or even "resistant" to the tested concentration of antibacterial drug, might still be effectively treated with the high concentration of drug achieved in the urine.

Although in vitro susceptibility testing is not always predictive of patient response to therapy for UTI, studies clearly show that patients infected with a resistant pathogen are at increased risk for treatment failure.[49,58–60] Clinical response to infection occurred in only 24% to 61% of patients with organisms resistant to TMP-SMX compared to 83% to 92% of patients infected with susceptible organisms[49,58,59]; furthermore, patients infected with TMP-SMX–resistant pathogens were 17 times more likely to fail therapy compared to patients with susceptible strains.[61] Infections with drug-resistant organisms also result in longer median times to symptom resolution (14 vs 7 days, $P = .0002$), more frequent clinic visits within 1 week (36% vs 6%, $P > .0001$), more frequent need for subsequent antibiotic therapy (36% vs 4%, $P > .0001$), and higher rates of significant bacteriuria after 1 month (42% vs 20%, $P = .04$).[59]

Although up to 75% of patients with organisms resistant to TMP-SMX may experience treatment failure with TMP-SMX, empiric antimicrobial therapy is usually chosen without C&S testing results. Appropriateness of antibiotic therapy is thus usually judged according to subsequent clinical response. If the infecting organism is susceptible, the urine will usually be sterile within 24 to 48 hours. If the urine specimen is sterile and the patient is symptomatically improved, the chosen antimicrobial is appropriate (regardless of susceptibility studies), and the full course of therapy should be completed. If a urine specimen collected 48 hours after initiation of therapy is not sterile and the patient has been taking the medication properly, the antibiotic may be inappropriate or the focus of infection may be deeper (eg, pyelonephritis, abscess, obstruction). Because V.Q. reports significant improvement in her subjective symptoms, she should complete her 3-day course of TMP-SMX as originally ordered and V.Q. should be closely monitored for any evidence of relapse. A repeat C&S test should be performed in the event that V.Q. reports any new signs or symptoms consistent with antibiotic failure and relapse of her infection, and a different antibiotic should be selected for treatment at that time.

FLUOROQUINOLONE THERAPY

CASE 71-2

QUESTION 1: I.B., a 48-year-old female, presents with a community-acquired UTI. She has a past medical history significant only for several previous episodes of UTI. A UA returns with the following results:

Appearance, straw-colored and turbid
Specific gravity, 1.028
pH, 6.3
Glucose, ketones, and bilirubin, all negative
Blood and protein, both trace positive by dipstick
WBC, 10 to 15 cells/LPF
RBC, 5 to 10 cells/LPF
Bacteria, many
Epithelial cells, 3 to 5 cells/LPF
Leukocyte esterase and nitrite test results by dipstick, both positive

Of note, I.B. has experienced a rash with TMP-SMX and a type I hypersensitivity reaction to penicillins in the past.

What is the role of fluoroquinolones in the treatment of I.B.'s community-acquired UTI?

Fluoroquinolones indicated for the treatment of uncomplicated or complicated UTI include norfloxacin, ciprofloxacin, and levofloxacin. They are usually administered orally in the treatment of UTI and have excellent in vitro activity against most gram-negative organisms, including *P. aeruginosa*.[62] They are also active in vitro against many gram-positive organisms including *S. saprophyticus*.[62] The in vitro activity of many fluoroquinolones is antagonized by acidic pH and divalent cations in urine; however, this is unlikely to be clinically significant because urine concentrations are several hundredfold greater than are serum levels.[62] Many clinical trials have demonstrated that fluoroquinolones are very effective in the treatment of acute uncomplicated UTI, with efficacy rates typically >90%.[20,51]

Although the fluoroquinolones are as effective as TMP-SMX, nitrofurantoin, or β-lactams in treatment of uncomplicated UTI, they are no longer recommended as first-line empirical therapy because they are more expensive and provide no additional treatment benefits.[5,8,20,51,62] Concerns also exist regarding the overuse of fluoroquinolones and the promotion of drug resistance among community-acquired uropathogens. Resistance to fluoroquinolones among organisms causing acute uncomplicated UTI is usually <1% to 2%.[21] Fluoroquinolone resistance may, however, be more frequent in some geographic areas and in complicated infections.[43–48] Recent studies revealed resistance to ciprofloxacin in 2% to 20% of acute uncomplicated infections, whereas it is 8% to 60% in complicated UTI.[20,43–48] Furthermore, these quinolone-resistant strains often are resistant to multiple other antimicrobials.[43–48] Concerns also exist regarding the potential for fluoroquinolones to produce collateral effects on normal flora, leading to increased risk of infection owing to MRSA and *C. difficile.*[20]

Fluoroquinolones are recommended as appropriate alternatives for patients with allergies or other contraindications to the use of recommended first-line agents or for patients infected with organisms resistant to multiple antibiotics, such as *P. aeruginosa.* Fluoroquinolones are appropriate initial therapy in geographic areas with >20% resistance of *E. coli* to TMP-SMX[20]; however, many patients in such areas may be appropriately treated with nitrofurantoin or other options (Table 71-3).[20] Further, the fluoroquinolones are effective in treating patients with structural or functional abnormalities of the urinary tract and other complicated infections.[20,62]

A fluoroquinolone may be considered for I.B. because she has experienced previous adverse reactions to penicillins and sulfonamides. However, nitrofurantoin or fosfomycin should be preferentially considered for I.B. based on current IDSA/ESMID recommendations.[20] If a fluoroquinolone was deemed appropriate for I.B. based on availability, cost, or tolerability issues with other treatment options, the individual fluoroquinolones are similar in efficacy, and the choice would be based on comparative costs and compliance considerations.[20] The duration of fluoroquinolone therapy in I.B. would be 3 days.[20]

NITROFURANTOIN-INDUCED ADVERSE EFFECTS

Case 71-2, Question 2: The decision is made to begin I.B. on nitrofurantoin rather than on a fluoroquinolone. After starting Macrobid® (nitrofurantoin monohydrate/macrocrystals) 100 mg twice daily (bid), she reports nausea and gastrointestinal (GI) upset after the ingestion of each dose. How can these GI effects be minimized in I.B.? What other important adverse effects are associated with nitrofurantoin?

Nausea is a common complication of nitrofurantoin therapy, and this may affect the patient's adherence with the prescribed regimen. It is unknown whether the mechanism by which nitrofurantoin produces nausea is central or local. Taking nitrofurantoin with food may reduce nausea, either by serving as a buffer or slowing the rate

of absorption and reducing peak concentrations of the drug. The macrocrystalline preparation (Macrodantin®) reduces GI adverse effects through slowing rates of dissolution and absorption and producing lower serum levels. Its disadvantage, however, is four times daily dosing and higher cost than the monohydrate/macrocrystalline preparation. The best-studied and clinically effective dose of nitrofurantoin is 100 mg bid,[20] which I.B. is currently receiving. I.B. should remain on her current product and dose; taking the drug with food should allow her to successfully finish her course of nitrofurantoin.

Several hundred cases of nitrofurantoin-induced acute, subacute, or chronic pulmonary reactions have been reported.[63] Acute toxicity often manifests with a sudden flulike syndrome consisting of fever, dyspnea, and cough within several days of initiating the drug; eosinophilia may also be present. The subacute form (fever and dyspnea) usually occurs after at least a month of exposure. The chronic form tends to be more insidious, with milder dyspnea and low-grade fever. In all forms, rales are common and pulmonary infiltrates may be present on chest radiograph.[63] Discontinuation of nitrofurantoin results in complete symptomatic recovery after several weeks; however, permanent fibrotic changes may persist with chronic pulmonary reactions. Rechallenge with oral nitrofurantoin results in rapid reappearance of pulmonary symptoms in those who have had an acute reaction; therefore, the drug must be avoided in patients with a history of nitrofurantoin-induced pulmonary toxicity.[63]

Peripheral neuropathy may also occur during prolonged nitrofurantoin therapy and is characterized by symmetric dysesthesia and paresthesia in the distal extremities, which progresses in a central and an ascending manner.[53],[64] Neuropathy usually occurs within the first 60 days of chronic nitrofurantoin treatment and is rarely seen during shorter courses of therapy.[53],[64] Symptom severity is not dose related and is generally reversible, although more severe cases may require up to several months to resolve completely. Renal failure is a risk factor for both neurotoxicity and pulmonary toxicity, but neuropathy has also been reported in patients with normal renal function.[53],[64]

FLUOROQUINOLONE USE IN PEDIATRIC INFECTIONS

CASE 71-3

QUESTION 1: C.S. is a 2-year-old female with a history of multiple recurrent UTIs caused by congenital urinary tract abnormalities that have not been corrected. She has had at least nine UTIs since birth and has received multiple courses of antibiotics, including ampicillin, amoxicillin, amoxicillin–clavulanate, and TMP-SMX. She has also been on chronic, low-dose antibiotic prophylaxis with TMP-SMX. C.S. was brought to her pediatrician 48 hours ago with signs and symptoms consistent with a new UTI. Suprapubic aspiration was performed, and urine samples sent for C&S testing at that time; C.S. was empirically begun on amoxicillin–clavulanate pending laboratory test results. C&S results, however, are now available and show $>10^5$ colonies/mL of *P. mirabilis.* The organism is susceptible to ciprofloxacin, gentamicin, and ertapenem and resistant to ampicillin, trimethoprim, TMP-SMX, cephalexin, cefaclor, cefpodoxime, tetracycline, nitrofurantoin, and erythromycin. C.S. has not clinically improved while receiving empiric amoxicillin–clavulanate.

What antibiotic therapy would be most appropriate for continued management of this acute infection in C.S.?

This case illustrates the serious dilemmas caused by antibiotic resistance among uropathogens. The pathogen isolated from C.S. is resistant to all commonly used, orally administered antibiotics that have been proved effective in the treatment of UTI in pediatric patients. Penicillins, cephalosporins, nitrofurantoin, and sulfonamides are frequently recommended for treatment of pediatric UTI; however, multiple past treatment regimens and chronic antibiotic prophylaxis make these agents less suitable for treatment of this new infection in C.S. Although in vitro susceptibility testing does not accurately predict clinical response to therapy in all cases, the risk of treatment failure and poor patient outcome is significantly increased when agents to which isolates are resistant are administered.[58,59] Alternative treatment is required; however, few desirable options exist for C.S.

The recommended duration of antibiotic therapy in C.S. would be at least 2 weeks for the treatment of this complicated and recurrent infection (refer to subsequent sections of this chapter). Although the organism isolated from C.S. is susceptible to gentamicin and this

drug would be effective, parenteral (intramuscular or intravenous [IV]) administration would be required and the lengthy required treatment duration makes this far from ideal. Use of aminoglycosides would also be less desirable because of toxicity concerns. Although ertapenem would also likely be effective, there is relatively little clinical experience with this agent in the pediatric population, and ertapenem would also require parenteral administration for the duration of the treatment regimen.

Fluoroquinolones are contraindicated in children and adolescents younger than 18 years of age because of concerns regarding potential musculoskeletal toxicities in juvenile populations. Although not approved for pediatric use, fluoroquinolones have been formally studied for febrile neutropenia, infectious gastroenteritis, otitis media, bacterial meningitis, and other uses in pediatric patients.[65–68] Use of fluoroquinolones has substantially increased in children and adolescents, most likely owing to resistance to other antimicrobials. Approximately 520,000 prescriptions were written in the United States for patients younger than age 18 years during 2002, including nearly 3000 prescriptions for children younger than 2 years, whereas an estimated 6.2 million additional prescriptions were written for children between 2006 and 2015.[65,66] Several reviews summarized data related to the safety of fluoroquinolones in children. Although tendinopathy or other musculoskeletal toxicities have been recorded, these toxicities were usually mild, reversible, and occurring at rates comparable to that seen in adults.[65,67,68] Based on currently available information and in consideration of antimicrobial resistance, the American Academy of Pediatrics has published recommendations regarding the use of fluoroquinolones in children and adolescents.[65] These indicate that fluoroquinolones may be considered in special circumstances including (a) infections caused by MDR pathogens for which there are no other safe and effective alternatives and (b) times when parenteral therapy is not feasible and no other effective oral agent is available. Treatment of UTI caused by MDR, gram-negative pathogens are specifically mentioned as a potentially appropriate use for fluoroquinolones in pediatric patients.[65]

Selection of a specific agent for the treatment of UTI in C.S. should be based on careful consideration of potential risks and benefits of available antibiotic options. The feasibility, risks, expenses, and inconvenience associated with prolonged (≥2 weeks) parenteral administration of an aminoglycoside or carbapenem are problematic; however, the ease of oral fluoroquinolone administration must be carefully balanced against the possible risks of using these agents in C.S. Clearly, no antibiotic of choice exists for treatment of C.S. and both the providers and the child's parents must be involved in development of an acceptable and well-informed treatment plan.

TREATMENT OF LOWER TRACT INFECTION IN RENAL FAILURE

CASE 71-4

QUESTION 1: K.M., a 55-year-old male with a history of hypertension and chronic renal failure, experiences a UTI. His creatinine clearance, determined from a recent 24-hour urine collection, is 20 mL/minute.

What antimicrobial agent should be prescribed?

The major problem in treating UTI in patients with renal failure is how to achieve adequate urine concentrations of the drug without causing systemic toxicity. The ideal drug would be (a) inherently nontoxic, even at high serum concentrations, making dosage adjustments unnecessary; (b) excreted unchanged in the urine (ie, not metabolized); and (c) eliminated by renal tubular secretion rather than by glomerular filtration. Because renal tubular secretion remains active in all but the most severe cases of renal failure, antibiotics eliminated by this mechanism would reach adequate urinary levels; however, no such ideal drug exists.

Nitrofurantoin and many sulfonamides are substantially metabolized by the liver and generally produce low urine levels in uremic patients. The aminoglycosides are eliminated almost

exclusively by the kidneys, but patients with uremia are at high risk for drug-induced toxicities and alternative agents are usually recommended. Penicillins, cephalosporins, and trimethoprim are partially metabolized by the liver but are also eliminated by the kidney to a significant extent. These agents are suitable for use in renal failure according to the criteria described earlier. Certain fluoroquinolones, specifically ciprofloxacin and levofloxacin, are highly excreted in the urine through a combination of filtration and tubular secretion and reach extremely high urinary concentrations. These agents are also considered safe and effective in the treatment of UTI in patients with renal failure. For suitable antibiotics, appropriate dosing for reduced renal function needs to be considered.

Acute Pyelonephritis

SIGNS AND SYMPTOMS

CASE 71-5

Question 1: L.B., a 45-year-old female with type 1 diabetes mellitus, comes to the emergency department with severe nausea, frequent vomiting, frequent urination, fever, shaking chills, and flank pain. Positive physical findings include a temperature of 103 °F (39.44 °C), a pulse of 110 beats/minute, blood pressure of 90/60 mm Hg, and CVA tenderness. A Gram stain of L.B.'s urine reveals gram-negative rods, and a UA demonstrates glucosuria, macroscopic hematuria, 20 to 25 WBC/LPF, numerous bacteria, and WBC casts. She also has a blood glucose level of 400 mg/dL. L.B. is admitted to the hospital with a diagnosis of acute bacterial pyelonephritis, and routine laboratory tests including a blood chemistry profile, complete blood count with differential, and specimens of urine and blood for C&S are ordered. L.B. is started on IV normal saline, ampicillin 1 g IV every 6 hours, and a sliding scale schedule of regular insulin based on every 6-hour blood glucose levels.

Which signs and symptoms in L.B. are consistent with pyelonephritis?

It is not always possible to differentiate clinically between upper and lower UTIs. Symptoms common in lower UTI often are the only positive findings in upper UTI (ie, subclinical pyelonephritis).[1–5,38,69]

L.B., however, does manifest signs and symptoms of systemic infection consistent with acute bacterial pyelonephritis, including tachycardia, hypotension, fever, nausea and vomiting, shaking chills, flank pain, CVA tenderness, hematuria, and WBC casts. In addition, her diabetes predisposes her to various renal infections, including pyelonephritis.[2–5,69]

Treatment

TRIAGE FOR HOSPITALIZATION

Case 71-5, Question 2: Why was L.B. hospitalized?

Most patients with pyelonephritis have relatively mild infection and can be treated as outpatients. The need for hospitalization often is determined by the patient's social situation and ability to maintain an adequate fluid intake and tolerate oral medications.[2–5,8,20] Patients who experience significant nausea and/or vomiting may not be able to maintain adequate hydration and thus may be at higher risk for cardiovascular complications of infection. Such patients may also require parenteral therapy initially for adequate empirical treatment. Finally, patients such as L.B. with diabetes should be hospitalized because acute pyelonephritis may predispose her to diabetic ketoacidosis.

Although blood cultures are usually obtained in patients with moderate-to-severe pyelonephritis, one study found that blood cultures were of low yield in the setting of acute uncomplicated pyelonephritis. They rarely provided any additional information not already obtained from the urine culture and were not helpful in the clinical management of such cases.[70] Blood cultures may be positive in up to 25% of patients with severe or complicated pyelonephritis, however, and they are still recommended for hospitalized patients such as L.B.[2–5,69,70]

ANTIMICROBIAL CHOICE FOR PYELONEPHRITIS

Case 71-5, Question 3: Was ampicillin appropriate treatment for L.B.?

Ampicillin is not an appropriate choice for L.B. because patients with diabetes (and patients treated with corticosteroids) are susceptible to colonization with unusual or more resistant organisms. As with lower tract UTI, pyelonephritis is often classified as uncomplicated or complicated. L.B.'s infection would be classified as a complicated infection because of her underlying diabetes.[2–5,8,20,69]

E. coli remains the predominant pathogen in complicated pyelonephritis, but other gram-negative organisms (eg, *Klebsiella*, *Proteus*, *Pseudomonas*) are frequently found.[2–5,8] Because L.B. is acutely ill and has gram-negative organisms in her urine, she should be treated with an antibiotic that has a better spectrum of activity against gram-negative organisms. Because of high rates of ampicillin resistance among common uropathogens, ampicillin and amoxicillin are inappropriate as empirical therapy for UTI, including pyelonephritis.[20] Current IDSA/ESMID recommendations for the initial oral management of acute pyelonephritis are shown in Table 71-3. Because L.B. is hospitalized, broad-spectrum parenteral antibiotics appropriate for initial therapy include third-generation cephalosporins (eg, ceftriaxone), fluoroquinolones (eg, ciprofloxacin, levofloxacin), extended-spectrum penicillins (eg, piperacillin–tazobactam), or carbapenems.[2–5,8,20] Aminoglycosides may be used empirically as either monotherapy or in combination with various β-lactams: in combination with ampicillin to provide better activity against suspected enterococci, or together with cephalosporins or piperacillin–tazobactam to provide enhanced gram-negative activity.[20] The choice of a specific regimen is based on local susceptibility patterns and should be tailored according to C&S test results.[20] It is not always necessary to initially treat patients with antipseudomonal therapy; thus, agents such as ceftriaxone with little activity against *Pseudomonas* are often appropriate as initial therapy in patients such as L.B.[4,8,20] Most hospital laboratories can report C&S results within 48 hours, and, accordingly, initial antibiotics can be replaced with more specific ones.

SERUM VERSUS URINE CONCENTRATIONS

CASE 71-5, QUESTION 4: Is it necessary to achieve bactericidal concentrations of antimicrobials in the serum, or are high urinary concentrations adequate for L.B.? How long should she be treated? How should therapeutic success be determined?

In patients with pyelonephritis and infection of the renal parenchyma, adequate tissue concentrations of antimicrobial agents are necessary. Therefore, antibiotics that achieve bactericidal concentrations in serum and kidney tissues as well as in the urine should be selected.[20,71] Patients requiring hospitalization should be treated with parenteral antibiotics until fluids and medications can be taken orally and the patient is symptomatically improved and afebrile for 24 to 48 hours.[2–5,38] This should be followed with a course of oral antibiotics for a total duration of antimicrobial therapy for ~14 days; less severe infections not requiring hospitalization are usually treated with 7- to 14-day courses, depending on the specific agent chosen.[20,38] Although it is customary to observe the patient in the hospital for 24 hours after switching from parenteral to oral antibiotics before discharge, this is probably of limited benefit.[2–5,8,38] Specimens for C&S testing should be obtained on the second day of therapy (to rule out treatment failure), 2 to 3 weeks after the completion of therapy, and again at 3 months.[1,4]

For patients who have relapsed after 14 days, retreatment for 6 weeks usually is curative. There have been reports of successful retreatment of relapsed infection with only 5 days of treatment[70]; however, longer courses are recommended.[4,8,70]

ORAL THERAPY FOR PYELONEPHRITIS

CASE 71-5, QUESTION 5: Would oral therapy have been appropriate for the initial treatment of acute pyelonephritis in L.B.?

Patients with mild, acute pyelonephritis (no nausea, vomiting, or signs of sepsis) can be treated with oral antibiotics such as fluoroquinolones for 5 to 7 days, or with TMP-SMX for 14 days.[2–5,20] Oral fluoroquinolones are preferred agents for initial empirical therapy of acute pyelonephritis in patients not requiring hospitalization because of lower resistance rates among common uropathogens compared to TMP-SMX, and higher rates of clinical and microbiological efficacy compared to β-lactams.[20] Fluoroquinolones may be particularly useful for patients potentially infected with resistant organisms because of their excellent in vitro activity against gram-negative organisms and high kidney tissue concentrations (2- to 10-fold greater than serum).[38,62] However, fluoroquinolone resistance and risk of inappropriate initial therapy may be more common in certain geographic areas. If fluoroquinolone resistance among *E. coli* exceeds 10%, treatment for acute pyelonephritis should be initiated with an IV dose of extended-spectrum cephalosporin (ie, ceftriaxone) or an aminoglycoside, until C&S test results are known (Table 71-3).[20,38] Oral agents such as amoxicillin–clavulanate, cefuroxime, cefpodoxime proxetil, or cefdinir also can be used in this setting, but the most recent guidelines suggest that oral β-lactams are less effective than are other available options and their use is discouraged as first-line treatment options.[20,38]

Patients such as L.B. with evidence of bacteremia (eg, fever, shaking chills) or sepsis (eg, hypotension) should be hospitalized and treated with parenteral antibiotics[4,8,20] (see **Table 71-4**). L.B.'s frequent vomiting and potential inability to receive oral antibiotics would also make initial therapy with parenteral antibiotics more favorable. Although L.B. will be initially treated with parenteral antibiotics, early switch to oral therapy after as few as 1 to 4 days of treatment is recommended; clinical outcomes with oral antibiotics are similar to those achieved with continued parenteral therapy (ie, ≥5 days).[38,72]

Table 71-4
Parenteral Antimicrobial Agents Commonly Used in the Treatment of Urinary Tract Infections

Class	Drug	Average Adult Total Daily Dose[a]		Usual Dosage Interval[b]	Comments
		UTI	Maximum Dose		
Penicillins	Ampicillin	2–4 g	8 g	Every 4–6 hours	Use should be based on local susceptibility patterns.
	Ampicillin–sulbactam	6 g	12 g	Every 6 hours	
	Piperacillin–tazobactam	12 g (piperacillin component)	16 g (piperacillin component)	Every 6 hours	
First-generation cephalosporins	Cefazolin	1–3 g	6 g	Every 8–12 hours	More effective than second- or third-generation cephalosporins against gram-positive organisms
Second-generation cephalosporins	Cefuroxime	2.25 g	4.5 g	Every 8 hours	Intermediate between first- and third-generation cephalosporins against gram-negative organisms
Third-generation cephalosporins	Cefotaxime	3–4 g	8 g	Every 6–8 hours	Better coverage than first- and second-generation cephalosporins against gram-negative organisms Ceftazidime and cefepime most effective against *Pseudomonas*. All generations of cephalosporins ineffective against *Enterococcus faecalis* and methicillin-resistant staphylococci. *(Exception: ceftaroline; see subsequent text.)*
	Ceftriaxone	1 g	1g	Every 24 hours	
	Ceftazidime	1–3 g	6 g	Every 8 hours	

Class	Drug	Average Adult Total Daily Dose[a]		Usual Dosage Interval[b]	Comments
		UTI	Maximum Dose		
Fourth-generation cephalosporins	Cefepime	1–2 g	4 g	Every 12 hours	Ceftaroline has activity against methicillin-resistant staphylococci.
	Ceftaroline	1.2 g	1.2 g	Every 12 hours	
Carbapenems	Imipenem–cilastatin	1 g	2 g	Every 6 hours	The most broad-spectrum coverage of any antibiotics listed. Ertapenem is not active against *Pseudomonas*. Resistance may develop, especially with *Pseudomonas*. Toxic in some pregnant animals
	Meropenem	1.5–3 g	3 g	Every 8 hours	
	Ertapenem	0.5–1 g	1 g	Every 24 hours	
Monobactam	Aztreonam	1–3 g	6–8 g	Every 8–12 hours	Active against gram-negative aerobic pathogens, including *Pseudomonas* sp.
Aminoglycosides	Gentamicin	3–5 mg/kg	5 mg/kg	Every 24 hours	Potent against gram-negative bacteria including *Pseudomonas*. Associated with possible eighth nerve toxicity in the fetus. Amikacin should be reserved for multiresistant bacteria.
	Tobramycin	3–5 mg/kg	5 mg/kg	Every 24 hours	
	Amikacin	7.5 mg/kg	15–20 mg/kg	Every 24 hours	
Quinolones	Ciprofloxacin	400–800 mg	800 mg	Every 12 hours	Use for resistant organisms. Change to oral therapy when indicated.
	Levofloxacin	500 mg	750 mg	Every 24 hours	

UTI, urinary tract infection.

[a]Higher doses are reserved for severe, potentially life-threatening infections or infections caused by organisms with reduced antibiotic susceptibilities and limited treatment options.

[b]Assuming normal renal function. Dose adjustments necessary in patients with compromised renal function (see Chapter 62, Principles of Infectious Diseases).

RECURRENT URINARY TRACT INFECTIONS

Relapse Versus Reinfection

CASE 71-6

QUESTION 1: T.W. is a 28-year-old female with a history of recurrent UTIs who now exhibits a new *E. coli* UTI. Her last episode occurred 5 months ago. Her current infection is treated with TMP-SMX for 10 days. A repeat UA was scheduled but she canceled her appointment because she "felt fine." Twelve weeks later, she returns to the clinic with signs and symptoms of another UTI. The only other medication she has taken is an oral contraceptive.

Why would C&S testing of a urine sample be especially useful at this time?

Recurrent infections develop in ~20% to 30% of females with acute cystitis.[3,5,34,38,73,74] Repeat C&S data should help determine whether this infection represents a relapse or a reinfection. Relapse refers to a recurrence of infection caused by the same microorganism that was present before initial therapy. Most relapses occur within 1 to 2 weeks of the completion of therapy and are caused by persistence of the organism in the urinary tract. Relapses often are associated with an inadequately treated upper UTI (eg, medication nonadherence), structural abnormalities of the urinary tract, or acute or chronic bacterial prostatitis in males.[1,34,38,73,74]

Reinfection implies recurrence of UTI with a different organism than was present before therapy. Reinfections can occur at any time during or after the completion of treatment, but most appear several weeks to several months later. Approximately 80% of recurrences are caused by reinfection.[1,34,38] Reinfection is generally caused by introital colonization with Enterobacterales from the lower intestinal

tract[1]; of these, *E. coli* is the most common. Certain *E. coli* strains have been shown to adhere to vaginal epithelial cells and, in females with recurrent UTI, adherence of these organisms to epithelial cells is increased.[26] Considering T.W. was symptom free for 8 weeks suggests that this is a reinfection, rather than a relapse. Patients with reinfection should be evaluated for modifiable predisposing factors such as use of a diaphragm with or without spermicides. Other risk factors for frequent reinfections include anatomic abnormalities, undiagnosed glucose intolerance, or diabetes.

Treatment for Reinfection

Case 71-6, Question 2: Pending the C&S test results, what therapy should be instituted in T.W.?

T.W. has a history of recurrent infections and now probably has a reinfection. Because reinfection is not caused by failure of previous therapy, TMP-SMX may be a reasonable choice once again. The probability that a resistant organism will be responsible for the infection increases when the interval between infectious episodes is short. If several months elapse between each episode of antimicrobial therapy, normal fecal bacterial flora becomes reestablished, and this reduces the risk of infection with resistant pathogens.

The alteration of fecal flora caused by the sulfonamides makes these drugs poor choices for repeated use in cases of frequent reinfection, especially when C&S results are unknown. The development of bacterial resistance also may limit the usefulness of these agents for chronic antimicrobial therapy.[20,34,38,73–75] However, because T.W.'s most recent infection was 12 weeks ago and the UTI before that was 5 months earlier, TMP-SMX would again be a reasonable choice at this time.

Case 71-6, Question 3: If T.W. exhibited an adverse reaction to TMP-SMX, what are the other therapeutic alternatives?

Nitrofurantoin is highly effective against *E. coli* with relatively low rates of resistance (<10%) in most geographic areas. It does not significantly alter the fecal or introital flora, and the emergence of resistance in previously sensitive strains does not often occur.[20,38,73–75] Therefore, it is generally a useful agent for the treatment of recurrent *E. coli*, *S. saprophyticus*, and *Enterococcus* infections.[20]

The fluoroquinolones also are useful in this setting, especially in geographic areas with high rates of TMP-SMX resistance.[34,72,74] However, their widespread use should be discouraged for reinfections as in T.W. in light of their high cost and concern regarding selection of resistant organisms.[20,34,74] Cephalosporins (eg, cefpodoxime proxetil) and trimethoprim have also been recommended as alternative agents in this setting.[3,73,74]

Antibiotic Selection for Treatment of Relapse

Case 71-6, Question 4: Greater than 10^5 bacteria/mL of *P. mirabilis*, sensitive to amoxicillin/clavulanate and TMP-SMX are cultured from T.W.'s urine. One week after completing her second course of TMP-SMX therapy, signs and symptoms of a UTI again appear. Pending C&S results, TMP-SMX is again prescribed. Is this still a reasonable medication for T.W. at this time?

Because the *P. mirabilis* cultured during the last recurrence was still susceptible to TMP-SMX, this agent would again be a reasonable choice until C&S test results are available. Alternatively, use of a different agent (eg, amoxicillin/clavulanate, nitrofurantoin, fluoroquinolone) could be considered because the relapse occurred within 1 week of completing the previous treatment and resistance may have developed.[5,34,75] Additional reasons for treatment failure, including failure to adhere to previously prescribed medication regimens, should also be investigated in patients with apparent recurrent infections.

Case 71-6, Question 5: How long should antibiotic therapy be continued in T.W. for her relapsed infection?

The duration of therapy for relapsing infections usually is 14 days. In patients who relapse after a second 2-week course of therapy, treatment for 6 weeks should be instituted.[1–3,34] If relapse occurs after a 6-week course, some experts recommend longer courses of 6 months to 1 year.[1–3] These prolonged courses should be reserved for children, adults with continuous symptoms, or adults at high risk for experiencing progressive renal damage. Asymptomatic adults without evidence of obstruction should not receive these longer courses. T.W. should be treated for at least 2 weeks and perhaps as long as 6 weeks.[34,74,75]

Case 71-6, Question 6: Although T.W. tolerated TMP-SMX well during her previous treatment, on this occasion she experiences significant nausea and vomiting after taking the medication. Would trimethoprim alone be an appropriate substitute for TMP-SMX in the treatment of T.W.'s infection?

Trimethoprim alone, and in combination with sulfamethoxazole, is active in vitro against many Enterobacterales associated with UTI and is an effective alternative to TMP-SMX in the management of both acute and chronic UTI.[1–3,5] It would be especially appropriate for T.W. because GI intolerance to TMP-SMX is most commonly attributed to the sulfamethoxazole component, and trimethoprim is associated with a lower incidence of side effects. Some concern exists for the potential development of resistant organisms, but studies using trimethoprim alone have failed to demonstrate a significant increase in bacterial resistance.[73,75] Trimethoprim is used for the treatment of acute, uncomplicated UTI in an oral dosage of 200 mg/day.

Chronic Prophylaxis

Case 71-6, Question 7: T.W. was treated successfully with trimethoprim for 6 weeks. Is prophylactic antimicrobial therapy indicated? If so, how long should it be continued?

Cases of chronic UTI in adult patients may be managed by treating each recurrent infection with an appropriate antibacterial drug or by administering chronic, low-dose prophylactic therapy. The frequency of urinary infections is the main determinant of whether chronic suppressive therapy should be used.[1,34,38,73–75] Long-term prophylactic therapy clearly reduces the frequency of symptomatic infections in nearly all patients.[15,34,38,73–75]

From a cost-effectiveness standpoint, females having more than one episode of cystitis per year may benefit from antimicrobial prophylaxis.[73] For females with three or more episodes of cystitis per year, prophylaxis clearly is more cost-effective than treating individual infections. Therefore, it is recommended that chronic antimicrobial prophylaxis may be considered in any adult patient with two or more episodes of UTI per year.[2,34,38,73–75]

The duration of prophylactic therapy also depends on the frequency of infection. Females with three or more UTIs in the 12 months before a 6-month course of antimicrobial prophylaxis have a significantly higher recurrence rate (75%) in the 6 months after prophylaxis is stopped compared to females with only two infections in the 12 months before prophylaxis (26% recurrence rate).[38] Therefore, prophylaxis should be continued for 6 months in patients with fewer than three UTIs per year, and for at least 12 months in adult patients with three or more UTIs per year.

Before initiating chronic antimicrobial suppressive therapy, active infections must be completely eradicated with a full course of appropriate antibiotic therapy. The low doses of antimicrobials used for chronic prophylaxis suppress bacterial growth but do not eliminate active infection. Furthermore, surgically correctable anatomic abnormalities that predispose the patient to recurrent infections (eg, obstruction, stones) should be ruled out.[34,38,73,75] Age also should be considered when contemplating chronic antimicrobial

therapy. An asymptomatic, elderly patient taking many other medications is usually not an ideal candidate for chronic prophylactic treatment because of problems of nonadherence, cost, and potential drug interactions or toxicities.[73,75] Younger patients, however, are good candidates for long-term suppressive therapy.[74,75]

Because T.W., a 28-year-old female, has had at least three UTIs in the past few months, has undergone extensive evaluation, and has just been successfully treated with a standard course of trimethoprim, a 12-month course of antimicrobial prophylaxis would seem reasonable. She also should be evaluated at regular intervals for recurrent UTI and for the development of resistant organisms.

Although the foregoing discussion applies to antimicrobial prophylaxis in adults, the use of long-term prophylaxis of recurrent UTI in children remains controversial. Individual studies have shown conflicting outcomes with respect to whether risk of recurrent UTI was significantly decreased. However, prophylaxis was associated with substantially increased risk of infection caused by resistant bacteria without any benefits related to decreased hospitalization, secondary infections, or evidence of parenchymal disease on renal scans.[76–80] A meta-analysis of 11 studies evaluating long-term antibiotic prophylaxis in children found no significant benefits of antibiotic administration overall.[76–80] Current recommendations are that long-term antimicrobial prophylaxis should not be routinely recommended for prevention of recurrent UTI in children.[1–3,73,74,76–80]

Case 71-6, Question 8: What drugs could be appropriately used for long-term suppressive therapy in T.W.?

Although numerous drugs are used for prophylaxis, TMP-SMX may be the drug of choice for chronic antimicrobial therapy owing to extensive experience, proven efficacy, infrequent toxicities, and low cost.[34,38,73–75] TMP-SMX also has the effect of decreasing vaginal colonization with uropathogens.[34,75] TMP-SMX single strength, either one-half or one full tablet daily, is commonly prescribed for chronic UTI prophylaxis and is an effective, well-tolerated, and convenient

prophylactic regimen.[34],[38],[73–75] Successful prophylaxis is significantly decreased in patients with urologic abnormalities or renal dysfunction. Also, infections that are not eradicated by a short-term therapeutic trial of TMP-SMX are not likely to respond to a long-term prophylaxis regimen.[38],[73] Finally, introital colonization with enterococci may occur in patients taking chronic TMP-SMX.[75]

Fluoroquinolones are effective for chronic suppressive therapy but should be used only when antimicrobial resistance or intolerance to other recommended drugs is present. Cephalosporins also have been recommended, but they are best reserved for patients intolerant to or failing prophylaxis with other agents.[73],[75]

When selecting a drug for chronic antimicrobial therapy, it is important to consider efficacy, the likelihood that resistant organisms will develop, long-term toxicity, convenience, and cost to the patient. The most commonly used agents are listed in **Table 71-5**.

Table 71-5

Antimicrobial Agents Commonly Used for Chronic Prophylaxis Against Recurrent Urinary Tract Infections

Agent	Adult Dose	Comments[a]
Nitrofurantoin	50–100 mg nightly	Contraindicated in infants <1 month of age. *To be taken with food or milk. May cause brown or rust-yellow discoloration of urine.*
Trimethoprim	100 mg nightly	Not recommended in children age <12 years.
Trimethoprim 80 mg + sulfamethoxazole 400 mg	0.5–1 tablet nightly *or* 3/week	Not recommended for use in infants ≤ 2 months. *To be taken on an empty stomach with a full glass of water. Photosensitivity may occur.*
Norfloxacin	200 mg/day	*To be taken on an empty stomach with a full glass of water; give at least 1 hour before or 2 hours after meal or dairy products. Do not coadminister with antacids or supplements/multivitamins containing di- or trivalent ions (give 2 hours before or after).* Monitor INR in patients receiving warfarin.

Cephalexin	125–250 mg/day	
Cefaclor	250 mg/day	

INR, international normalized ratio.

Based on the available information, T.W. could be switched to TMP-SMX. Although she has a history of GI distress because of this drug, it may not be a problem with the lower doses used for prophylaxis. If she is intolerant, trimethoprim alone, nitrofurantoin, or a fluoroquinolone also should be effective.

Cranberries and probiotics have long been of interest for their potentially beneficial effects in preventing UTI. Cranberries contain known compounds (ie, flavanols, anthocyanidins, proanthocyanidins-tannins) that prevent *E. coli* from adhering to uroepithelial cells in the urinary tract and may also inhibit bacterial motility.[74,80–83] A wide variety of cranberry products (eg, juice concentrate, juice cocktail, cranberry extracts in capsules and tablets) and different dosing regimens have been evaluated in the prophylaxis of UTI, but the overall inconclusive results preclude formal recommendations.[38,74,80–82] A 2012 meta-analysis found benefits of

cranberry-containing products in females (51% reduction in risk of infections), females with recurrent UTI (47% reduced risk of recurrences), and children (67% reduction in UTI risk).[81] However, this analysis also noted that available studies are quite heterogeneous, and the results of the meta-analysis should be interpreted with caution.[81] Recent consensus guidelines from the American Urological Association, Canadian Urological Association, and Society of Urodynamics, Female Pelvic Medicine & Urogenital Reconstruction (AUA/CUA/SUFU) state that cranberries may be offered for prophylaxis for recurrent UTIs, but this recommendation is conditional (ie, evidence indicates that there is no apparent net benefit or harm) and has a low strength of evidence.[74] Probiotics (particularly *Lactobacillus* strains) may prevent colonization with uropathogens.[38,80–83] Studies of probiotics for prophylaxis, however, are also inconclusive at this time. Lack of standardization of ingredients (ie, purity, dosage strengths) among available products and paucity of well-designed clinical studies are among the reasons for lack of clear recommendations regarding probiotics for this use. Further research is required to clarify unanswered questions regarding the role of cranberries or probiotics in the prevention of UTI.[38,80–83]

Urinary Tract Infection and Sexual Intercourse

CASE 71-7

Question 1: On routine screening, ASB is noted in W.W., a 30-year-old pregnant female in her first trimester. Five years ago, during her first pregnancy, she experienced acute bacterial pyelonephritis, which required hospitalization and treatment with parenteral antibiotics. Since that time, she has had recurrent UTIs, apparently related to sexual intercourse. These subsided when she began taking a single dose of nitrofurantoin after coitus, but she discontinued the practice before this pregnancy because she was afraid of the potential effects of this drug on the fetus.

What is the association between sexual intercourse and the occurrence of UTI?

Studies strongly support an association between sexual intercourse and UTI.[1–3,27] A direct relationship seems to exist between the number of days with intercourse within the previous week and the risk of developing a UTI.[1–3,27] One study found the relative risk of infection in females with 1, 4, and 7 days of intercourse within the previous week to be 1.4, 3.5, and 9.0, respectively, compared with females who were sexually inactive within the previous week. Another study found that the risk of UTI was doubled in females having intercourse more than four times a month compared with those females who did not.[27] Studies also indicate that introital colonization by fecal bacteria has a definite role in recurrent infections related to intercourse. The migration of these colonizing bacteria into the bladder appears to be facilitated during intercourse, but the exact mechanism remains unclear.[1–3] Because UTIs are uncommon in males, transmission of an infection from the male is unlikely. Occasionally, bacteria harbored under the foreskin of an uncircumcised male may be transmitted to his partner through intercourse.[25]

Case 71-7, Question 2: Was it rational to treat W.W.'s repeated infections with a single dose of an antibiotic after intercourse?

Postcoital antibiotic prophylaxis is useful when recurrent UTI results from sexual intercourse. Theoretically, a single dose of an antimicrobial agent produces bactericidal activity in the urine before bacteria have a chance to multiply, and the infection is averted. Patients should be instructed to empty their bladder just after intercourse and before taking the medication to minimize the number of bacteria present in the bladder and to reduce dilution of the drug in the urine. Because most drugs effective for UTI are rapidly excreted by the kidney and quickly reach high urinary concentrations, this regimen is reasonable and decreases the incidence of postcoital infections.[38,74] However, this practice is not recommended in patients with structural abnormalities of the urinary

tract or decreased renal function. Symptomatic infection must be completely treated before beginning prophylaxis.

Depending on the frequency of intercourse, postcoital prophylaxis may result in less antibiotic use compared with continuous prophylaxis. TMP-SMX and nitrofurantoin are the most commonly recommended agents; however, other agents such as fluoroquinolones and cephalexin may be used.[38,74]

Urinary Tract Infection and Pregnancy

Case 71-7, Question 3: Because W.W. is asymptomatic at this time, should treatment be withheld because of her pregnancy?

W.W. should be treated because acute symptomatic lower UTI or pyelonephritis may develop in pregnant females with untreated ASB. A clear cause-and-effect relationship between UTI and maternal or infant risk has not been definitely established.[84,85] However, treatment with an appropriate antimicrobial agent is currently recommended for all pregnant patients with significant bacteriuria, even when asymptomatic.[13,28,29]

The penicillins and cephalosporins are considered safe for use during pregnancy. However, these drugs, along with the others listed in Tables 71-3 and 71-5, cross the placental barrier; thus, the risk of toxicity or teratogenicity to the fetus must always be considered before deciding to treat a pregnant patient with a UTI.[88] Nitrofurantoin is often recommended during pregnancy because teratogenic effects have not been observed clinically and W.W. was previously using this agent for prophylaxis.[13,28,29,86] In vitro and retrospective investigations, however, suggest a mutagenic potential during the first trimester.[87,88] Although only small amounts of nitrofurantoin have been detected in breast milk, the drug could cause hemolytic anemia in a G6PD-deficient nursing infant.[88] Nitrofurantoin should therefore be used with caution during the first and late third trimesters. The fluoroquinolones are contraindicated in

pregnancy because of the arthropathy observed in immature animals.[62,88]

In this case, a cephalosporin or fosfomycin could be safely prescribed for treatment of W.W. Trimethoprim alone and TMP-SMX should be avoided in the first trimester because of the folate antagonist actions of trimethoprim and concerns regarding neural tube and cardiovascular defects potentially associated with maternal folate deficiency during the first trimester.[88] Although TMP-SMX may be an option during the second trimester, it should not be used after 32 weeks of gestation because of concerns regarding neonatal hyperbilirubinemia, jaundice, and kernicterus. W.W. was correct in discontinuing her nitrofurantoin before pregnancy because the risk to the fetus, although small, tends to offset the advantage of antimicrobial prophylaxis. W.W. must receive proper follow-up care.

Case 71-7, Question 4: For how long should W.W. be treated?

Few studies have compared single-dose and 3-day therapy with conventional 7-day therapy in pregnant patients. Although some clinical trials have shown single-dose therapy to effectively eradicate bacteriuria in pregnancy, most data suggest that cure rates of single-dose therapy were lower than 7- to 10-day therapy.[13,27–29,85] Therefore, similar to other populations, it is recommended that pregnant patients receive either a 3-day regimen or a prolonged (5- to 10-day regimen).[13,27–29,85]

Irrespective of the duration of therapy, appropriate follow-up of patients is crucial. Clinicians must document elimination of pathogens 1 to 2 weeks after therapy and follow up the patient monthly for the remainder of gestation. If bacteriuria recurs, therapy should be given for relapse or reinfection and the patient evaluated radiologically for structural abnormalities.[1,27]

ASYMPTOMATIC BACTERIURIA

Antibiotic Treatment

CASE 71-8

QUESTION 1: A.K., an asymptomatic 6-year-old female, is found to have significant bacteriuria on routine screening.

Should she be treated with an antimicrobial agent?

The treatment of patients with ASB depends on the clinical setting in which it is found. Recommendations for management of ASB are thus based on specific age, sex, and clinical characteristics and should consider the risk factors for development of acute UTI and subsequent long-term complications.[1,10,13,27–29] Generally, patients who benefit most from antibiotic treatment are those with urinary tract structural abnormalities, immunosuppressive therapy, and procedures requiring urinary tract instrumentation or manipulation.[1–3,13] Short-course regimens (ie, single-dose or 3-day ones) are usually recommended when treatment is desired,[3] although longer regimens have also been recommended.[13]

Although UTIs in infants and preschool children (predominantly females) are occasionally associated with renal tissue damage, its incidence is as low as 0.4% in children with previously normal renal function, and the overall risk of UTIs in this population is controversial.[9,89–91] However, ASB of childhood may be a manifestation of an anatomic or a mechanical defect in the urinary tract. Therefore, it should be evaluated fully. Because most cases of renal scarring as a result of bacteriuria occur within the first 5 years of life, it is controversial whether treatment should be limited to infants and preschool children or whether children should be treated regardless of age. Screening for bacteriuria in children and treating those with positive culture results, regardless of their clinical presentation, seems reasonable and is frequently recommended.[89–91] Treatment of A.K. seems prudent because any renal damage resulting from ASB generally occurs during childhood. Should the decision be made to treat, principles of therapy are similar to those for symptomatic infections.

Pregnant Patients, the Elderly, and Other Adult Populations

CASE 71-9

Question 1: B.F., a 65-year-old female, is found to have significant bacteriuria on routine screening before an elective surgery not involving the urinary tract. She has no symptoms associated with the bacteriuria.

Should she be treated with an antimicrobial agent? What other population groups should be treated for ASB?

Without urinary tract obstruction, UTIs in adults rarely lead to progressive renal damage.[3,5] Therefore, ASB does not require treatment in most adult patients without evidence of mechanical obstruction or renal insufficiency. As previously discussed, antimicrobial therapy is appropriate during pregnancy because as many as 40% of pregnant females with ASB later develop symptomatic UTI, particularly pyelonephritis.[13] In addition, studies have confirmed associations between acute pyelonephritis during pregnancy with increased rates of preterm labor, premature delivery, and lower birth-weight infants.[27] The treatment of ASB in pregnancy is therefore justified to decrease the risk of associated complications.[13]

Bacteriuria in elderly individuals such as B.F. is common; about 20% of all females and 10% of all males ages 65 years and older have bacteriuria.[14–16] Although bacteriuria in this population often leads to symptomatic infection, clinical studies have not consistently documented beneficial outcomes in treated patients compared with untreated patients.[13,15] Consequently, therapy is not recommended for the asymptomatic older patient because the expense, side effects, and potential complications of drug therapy appear to outweigh the benefits.[13,15] Patients experiencing symptomatic infections should be treated as usual.

The treatment of ASB in females with diabetes does not reduce complications and is not currently recommended.[13,28]

HOSPITAL-ACQUIRED ACUTE URINARY TRACT INFECTION

CASE 71-10

QUESTION 1: P.M., an alert, 70-year-old female with chest pain, was hospitalized to rule out acute myocardial infarction. This is her third hospitalization for chest pain in the past 6 months. A urinary catheter was temporarily placed as part of her routine medical care. Two days after admission and one day after removal of the urinary catheter, she reported burning on urination and bladder pain. TMP-SMX double-strength, one tablet bid was ordered after the microscopic examination of the urine indicated a UTI.

Was this empiric therapy appropriate?

Hospital-acquired (or nosocomial) UTIs occur in about 500,000 patients per year, and most are associated with the use of indwelling bladder catheters. Approximately 10% to 30% of catheterized patients experience infection.[23] Complications of CAUTI are considerable and include bloodstream infections with increased mortality rates, increased hospital length of stay, and increased hospital costs. Prevention is the best way to manage nosocomial UTI, but antibiotic treatment is usually initiated in hospitalized patients who exhibit UTI symptoms.

The susceptibility of hospital-acquired pathogens to antimicrobial agents differs from community-acquired bacteria, and these susceptibilities frequently vary from one hospital to another. Therefore, the microbiology department of a particular hospital should be consulted to determine current trends in the antibiotic susceptibility of bacteria acquired in that setting. In general, *E. coli* is still the predominant urinary tract pathogen. An increased proportion of infections is caused, however, by other gram-negative bacteria such as *Proteus* and *Pseudomonas*, gram-positive pathogens such as *Staphylococcus* and *Enterococcus*, and yeast (eg, *Candida*).[21,23]

Repeated courses of antibiotic therapy, anatomic defects of the urinary tract, old age, increased length of hospital stay, and repeated hospital admissions are associated with a higher incidence of

infection with antibiotic-resistant organisms.[21,23,92] *Pseudomonas*, *Proteus*, *Providencia*, *Morganella*, *Klebsiella*, *Enterobacter*, *Citrobacter*, and *Serratia* and ESBL uropathogens are particularly difficult to eradicate because they usually are less susceptible to commonly used antimicrobial agents.

P.M. is elderly, hospitalized, and has been repeatedly exposed to potentially resistant organisms during her previous hospitalizations. Oral fluoroquinolones are most commonly used as empiric therapy in this setting because of their greater activity against potentially resistant pathogens compared to TMP-SMX; however, fluoroquinolone use is often discouraged in older patients owing to a greater risk of adverse effects such as central nervous system toxicities and QTc interval prolongation. Therefore, TMP-SMX is an acceptable empirical therapy in P.M. as long as her clinical and laboratory data are appropriately monitored.[21,23,93] A C&S test of P.M.'s urine should be performed and once results are known, therapy promptly changed accordingly. To achieve the most cost-effective therapy, oral agents should be administered to all patients capable of taking medications by mouth, unless the isolated pathogens are resistant to oral medications, or underlying GI dysfunction makes adequate absorption of oral antibiotics questionable.[23,69,93] The recommended duration of antibiotic therapy for patients such as P.M., who present with mild-to-moderate symptoms, is 5 to 7 days; patients who do not respond promptly to treatment may be treated for a total of 10 to 14 days.[23]

In seriously ill patients with possible sepsis, broad-spectrum parenteral antibiotics with activity against *P. aeruginosa* are usually preferred as initial therapy (Table 71-4). In general, antipseudomonal β-lactam antibiotics remain the empiric drugs of choice for nosocomial urologic sepsis.[93] Because many patients may be at risk for infection caused by MDR pathogens, C&S test results should carefully monitored, and therapy adjusted accordingly. Although combination therapy may be useful initially in patients with neutropenia with urologic sepsis, it should be narrowed to single-agent therapy once culture results are available.[93] The

recommended duration of antibiotic therapy in seriously ill patients is 10 to 14 days.[23]

Catheter-Associated Urinary Tract Infection

CASE 71-11

QUESTION 1: J.W., an 18-year-old female, was hospitalized after a diving accident that resulted in a spinal cord injury with paralysis. Included among several initial interventions was insertion of an indwelling catheter with a closed drainage system because of bladder incontinence. Two weeks after admission to the hospital, J.W. has developed ASB.

Should this be treated?

A systemic antibiotic selected specifically for the infecting organism will temporarily result in sterile urine. Reinfection, often by a resistant organism, then occurs in 30% to 50% of these cases if closed drainage catheterization is continued during therapy.[1,23] For this reason, it generally is recommended that systemic antimicrobial therapy be initiated after or just before catheter removal in those patients in whom antibiotics are needed.[1,23,94] Because long-term catheterization is necessary in many patients and because bacteriuria is an inevitable consequence, asymptomatic patients (such as J.W.) should be left untreated to avoid the complications of recolonization and potential infection with resistant organisms.[1,13,23,94] Therapy must be started, however, if fever, flank pain, or other symptoms indicative of an actual UTI develop.[1,23]

CASE 71-11, QUESTION 2: Is systemic antimicrobial prophylaxis useful for J.W.?

The benefits of systemic antibiotics in preventing CAUTI are not clear. Studies using closed drainage systems with diligent catheter care indicate that systemic antibiotics decrease the daily and overall incidence of infection in patients with sterile urines before catheterization.[35,36] The preventive effect of antimicrobials is greatest

for short-term catheterizations or during the first 4 to 7 days of long-term catheterization.[35],[36] Thereafter, the rate of infection increases despite antibiotics. Although the overall infection rate remains lower than in untreated patients, the emergence of resistant organisms is significant. Therefore, in deciding to use systemic antimicrobials, it is important to consider the patient's underlying diseases, risk factors, probable duration of catheterization, and potential complications of drug toxicity or resistant organisms that can result from the chronic use of antimicrobials. Because long-term catheterization is anticipated for J.W., antimicrobial prophylaxis for J.W. is not recommended.[23]

Case 71-11, Question 3: J.W. eventually regains urinary continence and the catheter is removed. However, 2 days after removal of the catheter, she still has ASB. How should she be managed?

Because ASB in patients with urinary catheters is very common (~25% with short-term catheterization and virtually 100% long term) but is associated with few complications, antibiotic therapy for ASB is not recommended as long as the catheter remains in place.[23] However, antibiotic treatment may be considered in asymptomatic females with catheter-acquired bacteriuria that persists >48 hours after catheter removal.[13],[23] Such patients can be treated with either a single large dose or a 3-day regimen of TMP-SMX, even if the patient is asymptomatic.[13],[23],[24] Older females (older than 65 years) probably should be treated with a 10-day course; however, the optimal duration in this age group is unknown. Whether these same treatment regimens are advisable in male patients requires further study.[23]

PROSTATITIS

Incidence, Prevalence, and Epidemiology

Prostatitis is an acute or chronic inflammatory condition affecting the prostate, with ~5% of cases being caused by proven bacterial infections.[11,12] Other noninfectious types of prostatitis include chronic calculus prostatitis, nonbacterial prostatitis, and prostatodynia.[11,12] Chronic bacterial prostatitis, defined as prostatitis in which symptoms persist for at least 3 months, is one of the most common causes of recurrent UTI in males. The lifetime probability of a male being diagnosed with prostatitis is >25%; recurrence rates reportedly range from 20% to 50%.[11,12] Approximately 5% of males with acute prostatitis will experience chronic infection.[11]

Etiology, Pathogenesis, and Predisposing Factors

ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis in most patients probably begins as an ascending infection of the urethra. A simple UTI then eventually involves reflux of infected urine into the ejaculatory and prostatic ducts through the prostate gland, where bacteria are difficult to eradicate.[12] Acute prostatitis may also result from urethral stricture or after instrumentation of the urinary tract or prostate biopsy, especially in the presence of bacteriuria at the time of the procedure.[12] Bacterial prostatitis is predominantly caused by aerobic gram-negative bacilli, with *E. coli* causing 50% to 90% of cases. Other Enterobacterales such as *Proteus* and *Klebsiella* account for an additional 10% to 30% of cases, followed by *Enterococcus* (5% to 10%) and *Pseudomonas* (>5%); less common causes include staphylococci, streptococci, and atypical organisms such as *C. trachomatis*, *T. vaginalis*, and *Ureaplasma urealyticum*.[11,12]

CHRONIC BACTERIAL PROSTATITIS

Chronic prostatitis is commonly associated with spinal cord injuries, infectious stones, anatomic or physiologic abnormalities of the urinary tract such as obstruction or voiding dysfunction, and immune dysfunction. However, recurrent infections are also commonly

caused by relapses of acute prostatitis due to persistent bacteria in the prostate.[11,12] Normally, males secrete a prostatic antibacterial factor; however, this substance is often absent or significantly reduced in males with chronic prostatitis. The most common pathogens isolated from chronic bacterial prostatitis are *E. coli* (>80% of cases) and other gram-negative bacilli, although atypical bacteria have also been more commonly reported in chronic prostatitis compared to acute infections.[11,12]

Clinical Presentation and Diagnosis

ACUTE BACTERIAL PROSTATITIS

Acute bacterial prostatitis is characterized by the sudden onset of chills and fever; perineal and low back pain; urinary urgency and frequency; nocturia, dysuria, and generalized malaise; and prostration. Patients may also report myalgias, arthralgias, and symptoms of bladder outlet obstruction. Rectal examination usually discloses an exquisitely tender, swollen prostate that is firm and warm to the touch. Culture of the voided urine generally identifies the pathogens. In patients with acute bacterial prostatitis, prostatic massage (see following discussion) should be avoided because of patient discomfort and the risk of bacteremia.[11,12] The diagnosis of acute prostatitis is therefore usually based on clinical presentation and physical examination.

CHRONIC BACTERIAL PROSTATITIS

The clinical manifestations of chronic bacterial prostatitis are highly variable, and many patients are asymptomatic. The disease usually is suspected when a male patient treated for UTI or acute prostatitis relapses. The diagnosis of chronic prostatitis is confirmed by examination of expressed prostatic secretions.[11,12] To ensure accurate localization (ie, to distinguish prostatic from urethral bacteria), segmented urine samples are taken. The first 10 mL of collected voided urine represents the urethral sample, the midstream urine represents the bladder sample, and the first 10 mL voided

immediately after prostatic massage represents the prostate sample. When the bladder sample is sterile or nearly so, bacterial prostatitis is diagnosed if the bacterial count in the prostate sample is at least one logarithm greater than that in the urethral sample.[11,12]

Overview of Treatment

Treatment of bacterial prostatitis is challenging because of poor penetration of many antibiotics across the nonfenestrated prostatic capillaries and through prostatic epithelium into infected tissues and fluids. Most acidic antibiotics do not readily cross the prostatic epithelium into the alkaline prostatic fluid except in the presence of acute inflammation. Theoretically, the high alkalinity of prostatic fluids should impair the diffusion of trimethoprim and enhance the diffusion of tetracyclines, certain sulfonamides, and macrolide antibiotics, such as erythromycin. TMP-SMX is commonly used in the treatment of both acute and chronic prostatitis. Fluoroquinolones are often considered the preferred antibiotics for treatment of acute or chronic prostatitis because of good penetration into the prostate (10%–50% of serum concentrations) and good activity against most causative pathogens, although fluoroquinolone resistance has become a growing problem.[11,12] β-Lactams, tetracyclines, macrolides, and clindamycin have also been successfully used in the treatment of both acute and chronic infections, but their penetration into the prostatic tissues and fluids may be somewhat less than that of the fluoroquinolones or TMP-SMX. In addition, the antimicrobial activity of these drugs is not ideal for covering the most common causative pathogens.[11,12]

The duration of antibiotic therapy in acute prostatitis is 2 to 4 weeks, depending on the severity of the infection and rate of response to treatment.[11,12] Chronic prostatitis is usually treated for 4 to 6 weeks, although longer courses may be required in the presence of prostate stones or other types of genitourinary pathology, and long-term suppressive therapy is sometimes used for patients with a history of rapid and/or multiple recurrences.[11,12]

Monitoring parameters consist primarily of clinical signs and symptoms, and the treatment end point is complete resolution of clinical findings.[11,12]

Supportive treatment for prostatitis consists primarily of drugs for symptomatic relief such as acetaminophen or nonsteroidal anti-inflammatory agents; warm compresses to the perineal area are also recommended, although there are few data to support this practice.[11,12] Other supportive measures for symptomatic relief in patients with acute bacterial prostatitis include liberal hydration, sitz baths, and stool softeners.

CASE 71-12

QUESTION 1: D.G., a 60-year-old male, experienced his first UTI at age 40, with symptoms of frequency, dysuria, nocturia, perineal pain, fever and chills but no flank pain, and acute prostatitis being diagnosed. *E. coli* was cultured from the urine, and treatment with TMP-SMX was successful. Two more *E. coli* infections that responded to TMP-SMX therapy occurred during the next 8 years.

Why was TMP-SMX appropriate treatment for D.G.'s repeated acute episodes of bacterial prostatitis?

Many antibacterial drugs appropriate for UTI, including sulfonamides, can be used to treat acute bacterial prostatitis because the diffuse, intense inflammation of the prostate gland allows many of these drugs to readily penetrate into the prostatic fluid and tissues. In the case of D.G., these repeated episodes occurred far enough apart to be considered reinfections rather than relapses, which are often associated with treatment failures and development of antimicrobial resistance. The overall risk of D.G. developing resistance to sulfonamides subsequently remained relatively low. Antimicrobial therapy should be continued for at least 2 to 4 weeks to prevent the development of chronic prostatitis.[11,12,24]

CASE 71-12, QUESTION 2: Three years after the last episode of prostatitis, D.G. again starts to experience urinary frequency, dysuria, perineal pain, and fever. He is again diagnosed with acute bacterial prostatitis. What would be a reasonable choice of therapy for D.G.'s current episode of prostatitis?

In retrospect, sulfonamides were previously appropriate for D.G. because they effectively treated his past infections; a sulfonamide would potentially again be appropriate for future episodes. TMP-SMX historically has the best-documented cure rates in the treatment of acute and chronic bacterial prostatitis. Long-term therapy for chronic bacterial prostatitis with TMP-SMX for 4 to 16 weeks is associated with a cure rate of 32% to 71%, which significantly exceeds the cure rate associated with short-term therapy for ≤2 weeks.[11,12]

The fluoroquinolones are alternatives to TMP-SMX and are now considered by many to be the agents of choice for the treatment of prostatitis.[11,12,24] A number of studies have documented bacteriologic cure in 80% to 90% of patients treated with norfloxacin, ciprofloxacin, or levofloxacin for 4 to 12 weeks, rates comparable to or substantially higher than those achieved with TMP-SMX.[11,12] The fluoroquinolones are also excellent alternatives to other agents in patients who are unresponsive or intolerant to conventional therapy, or in those infected with resistant organisms.[11,12,24] Fluoroquinolones also have been used for chronic suppressive therapy (one-half normal doses) in patients who relapse after conventional treatment.[1]

D.G. should be treated with TMP-SMX for a minimum of 6 weeks; some authorities recommend a 2- to 3-month total course of therapy. If an adequate trial of TMP-SMX is unsuccessful, fluoroquinolone therapy can be used. Alternatively, a fluoroquinolone could be used as initial therapy for this or future episodes.[11,12,24]

If D.G. continues to experience recurrent infections after a trial of fluoroquinolone therapy, chronic low-dose treatment with TMP-SMX, fluoroquinolones, or nitrofurantoin can alleviate the symptoms of episodic bladder infection associated with chronic bacterial prostatitis. Infections eventually recur with greater frequency in most of these patients. Chronic, low-dose antibacterial therapy sterilizes the bladder, alleviates symptoms, confines bacteria to the prostate, and prevents infection of and damage to the rest of the urinary tract. Chronic bacterial prostatitis is one of the few indications for continuous antibiotic therapy.

Sexually Transmitted Diseases

Albert Bach, Anne Walsh, and Karl M. Hess

CORE PRINCIPLES		CHAPTER CASES
GONORRHEA		
1	Gonorrhea is initially characterized in males by a purulent discharge associated with dysuria. Discharge may become more profuse and blood tinged as the infection progresses. Some strains of gonorrhea have a propensity to cause asymptomatic or minimally symptomatic infections.	**Case 72-1 (Questions 1–3)** **Case 72-2 (Questions 1, 2)**
2	In females, the most common symptom of gonorrhea is vaginal discharge. Many females infected with gonorrhea have abnormalities of the cervix, including purulent or mucopurulent endocervical discharge, erythema, friability, and edema of the zone of ectopy. Pelvic	**Case 72-1 (Questions 4, 5)**

	inflammatory disease (PID) is a serious complication and can lead to infertility and chronic pelvic pain.	
3	The standard of treatment for gonorrhea is a third-generation cephalosporin such as ceftriaxone. Fluoroquinolones should not be used owing to high levels of resistance.	**Case 72-1 (Questions 6–8)** **Case 72-2 (Questions 3–5)**
4	In a small percentage of patients, gonococcal infections may invade the bloodstream and cause infections at distant sites in the body causing disseminated gonococcal infections (DGIs). The recommended treatment for DGI is ceftriaxone.	**Case 72-4 (Questions 1–4)**
	PELVIC INFLAMMATORY DISEASE	
1	PID may be treated on an inpatient or outpatient basis. Those with mild-to-moderate PID can be admitted and treated with parenteral antibiotics; however, clinical efficacy and overall outcomes are equal between parenteral and oral therapies.	**Case 72-3 (Question 1)**
	NONGONOCOCCAL URETHRITIS	
1	Nongonococcal urethritis (NGU) is a common sexually transmitted infection in males and is frequently caused by *Chlamydia trachomatis*.	**Case 72-5 (Question 1)**
2	NGU typically produces less severe and less frequent dysuria and less penile discharge as compared with gonococcal	**Case 72-5 (Question 2)**

	urethritis. NGU and gonococcal urethritis cannot be reliably differentiated on the basis of symptoms and signs.	
3	NGU may be treated with either azithromycin or doxycycline; however, azithromycin is superior in its coverage of both *Mycoplasma genitalium* and *Chlamydia*.	**Case 72-5 (Questions 3–5)**
	LYMPHOGRANULOMA VENEREUM	
1	Lymphogranuloma venereum is characterized by three stages of infection and may be treated with doxycycline, erythromycin base, or azithromycin.	**Case 72-6 (Questions 1, 2)**
	SYPHILIS	
1	Syphilis is characterized by four stages of infection: primary, secondary, latent, and tertiary. Penicillin G is the drug of choice for all stages of syphilis.	**Case 72-7 (Questions 1–5) Case 72-8 (Questions 1, 3)**
2	The Jarisch–Herxheimer reaction is a benign, self-limited complication of antibiotic therapy that may develop after treatment of primary and secondary syphilis.	**Case 72-8 (Question 2)**
	CHANCROID	
1	Uncircumcised males have an increased risk of infection and may not respond to therapy as well as circumcised males do. Current	**Case 72-9 (Questions 1, 2)**

	treatment options include azithromycin, ceftriaxone, ciprofloxacin, and erythromycin base.	
	VAGINITIS	
1	Common causes of vaginitis include bacterial vaginosis, trichomoniasis, and vulvovaginal candidiasis. General symptoms may include itching, burning, irritation, and abnormal discharge and can be differentiated based on signs, symptoms, and laboratory testing.	**Case 72-10 (Question 1) Case 72-11 (Questions 2–4) Case 72-12 (Question 1)**
2	Vulvovaginal candidiasis may be effectively treated with nonprescription medications; however, patients must be assessed fully before self-treatment is initiated.	**Case 72-11 (Questions 1–4, 6–9)**
	GENITAL HERPES	
1	Genital herpes, transmitted either from symptomatic or asymptomatic individuals, often presents with painful vesicles in those with herpes simplex virus type 2 primary infection, and recurrent infections are common, although the frequency decreases with time.	**Case 72-14 (Questions 1–3)**
2	Genital herpes is best treated with oral antivirals, such as acyclovir or valacyclovir, and prevented with either suppressive or standby antivirals.	**Case 72-14 (Question 5)**
	GENITAL WARTS	

1	Human papillomavirus is highly contagious and may now be prevented by vaccination, in addition to condoms.	**Case 72-17 (Question 1)**
2	Genital warts often recur even with treatment, which is primarily local, including antimitotics, immune modulators, chemical and surgical ablation, and cryotherapy.	**Case 72-17 (Question 1)**

INTRODUCTION

Sexually transmitted diseases (STDs) are discussed in the earliest written records. However, only in the past several decades have the common STDs been differentiated from each other; unique STD syndromes continue to be described today. For example, of the common STDs, herpes simplex virus (HSV) type 2 (the cause of genital herpes) was not differentiated from HSV type 1 until the 1960s; the spectrum of genital chlamydial infections was not defined until the 1970s; and the human immunodeficiency virus (HIV), as an STD, was not recognized until the 1980s. Since 1980, eight additional sexually transmitted pathogens have been identified. They include the human papillomaviruses (HPVs), human T-lymphotropic virus (HTLV-I and -II), *Mycoplasma genitalium, Mobiluncus* species, HIV-1 and -2, and the human herpesvirus type 8 (associated with Kaposi sarcoma).[1] More recently, the Centers for Disease Control and Prevention (CDC) reports that although hepatitis C virus (HCV) infection is not efficiently transmitted through sexual contact, MSM (men who have sex with men) coinfected with HIV are more likely to transmit HCV than through heterosexual contact.[2] See https://www.cdc.gov/std/training/default.htm for general resources from the CDC for various STDs.

GONORRHEA

Gonorrhea[3] is caused by *Neisseria gonorrhoeae,* a gram-negative diplococcus. Depending on the site of exposure, this disease can cause uncomplicated cervical, urethral, rectal, and oropharyngeal infections in both males and females. *N. gonorrhoeae* infection in females is also a major cause of pelvic inflammatory disease (PID). Disseminated gonococcal infection (DGI), the bacteremic spread of *N. gonorrhoeae* to joints and other tissues, can lead to complicated gonorrhea infections that cause pustular acral skin lesions, tenosynovitis, polyarthralgia, or arthritis. DGI may lead to rare cases of perihepatitis, endocarditis, or meningitis. In the 1930s, sulfonamides became the first form of effective antimicrobial therapy for gonorrhea until penicillins and tetracyclines became the mainstays of therapy; however, the high levels of resistance to these two antimicrobial agents have eliminated their use in the treatment of this disease state.

In the United States, the incidence of gonorrhea fell 74.3% between 1975 and 1997 after the establishment of national gonorrhea control programs. From 1996 to 2006, the rate fluctuated at around 115 cases per 100,000 individuals, and from 2006 to 2009, the rates declined to a historic low of 98.1 cases per 100,000 individuals in 2009.[4],[5] In 2018, gonorrhea cases yielded a rate of 179.1 cases per 100,000 population. From 2017 to 2018, the rate of reported gonorrhea cases increased 5.0% and increased 82.6% since the historic low in 2009.[6] From 2014 to 2018, the rates of reported gonorrhea cases increased for each of the 5 years among all race/Hispanic ethnicity groups. As of the 2018 Sexually Transmitted Disease Surveillance Report, rates of gonorrhea were highest among Blacks, followed by American Indians/Alaska Natives and Native Hawaiians/Other Pacific Islanders (**Fig. 72-1**).[6]

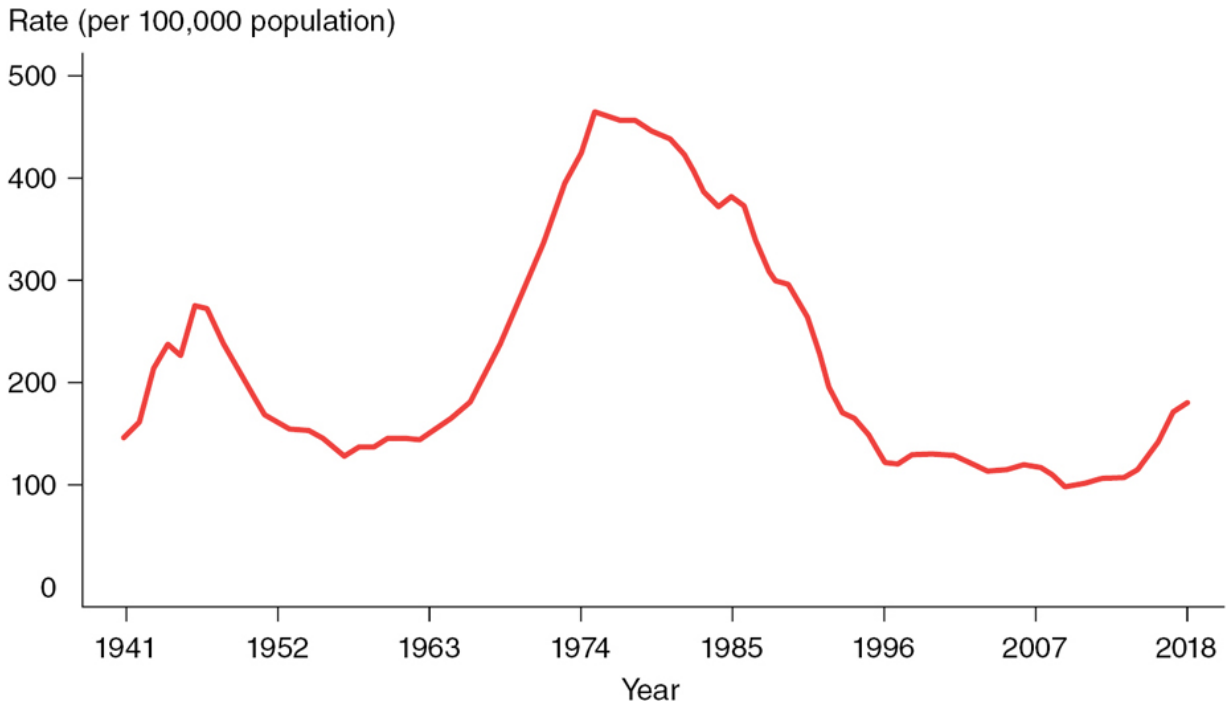

Figure 72-1 Gonorrhea rates by year in the United States. Line graph showing rates of reported cases of gonorrhea in the United States by year from 1941 to 2018. In 2018, gonorrhea cases yielded a rate of 179.1 cases per 100,000 population. From 2017 to 2018, the rate of reported gonorrhea cases increased 5.0% and increased 82.6% since the historic low in 2009. (From Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats18/figures/14.htm.)

In 2018, the highest incidence of gonorrhea was in males ages 20 to 24 years and in females ages 20 to 24 years.[6] Additional risk factors for females acquiring gonorrhea include a previous gonococcal or other STD infection, new or multiple sex partners, inconsistent condom use, or engaging in commercial sex work or drug use.[7] Although the risk of gonorrhea was greater in MSM than in MSW in the past, the incidence dropped in homosexual males during the 1980s AIDS epidemic because of a reduction in sexual risk behaviors. Currently, the incidence of gonorrhea in MSM continues to rise, with an estimated 375.5% increase during 2010 to 2018 from 1368.6 cases per 100,000 MSM in 2010 to 6508.0 cases

per 100,000 MSM in 2018. Comparing this to men who have sex with women (MSW) over the same period, case rates among MSW and women increased by 69.3% and 95.2%, respectively.[6]

Uncomplicated Gonorrhea

TRANSMISSION

CASE 72-1

Question 72-1: D.S., a 23-year-old male naval officer recently stationed in the Philippines, presents with dysuria, meatal pain, and a profuse yellow urethral discharge for 2 days. He admits to having sex with a sex worker during the past week. He is accompanied by his pregnant wife, C.S., who is asymptomatic. D.S. engages in insertive vaginal sex, but there is no history of oral or anal sex with either partner.

Assuming the sex worker has gonorrhea, what is the likelihood that D.S. and C.S. have been infected?

After one or two episodes of unprotected vaginal intercourse with an asymptomatic infected sex worker, a male has an ~50% risk of acquiring a urethral infection; the risk increases with repeated exposures and high prevalence among commercial sex workers.[8] The prevalence of infection in females who are secondary sex contacts of infected males is as high as 80% to 90%.[9] Therefore, the likelihood that D.S. and C.S. are infected is high. Because D.S. had sex with a sex worker, both D.S. and C.S. should also be tested for HIV infection.

SIGNS AND SYMPTOMS: MALES

Case 72-1, Question 2: What signs and symptoms in D.S. are consistent with the diagnosis of gonorrhea? Describe D.S.'s anticipated clinical course if he remains untreated.

In males, gonorrhea usually becomes clinically apparent 1 to 7 days after contact with an infected source. A purulent discharge associated with dysuria is the first sign of infection; D.S. exhibits both. The discharge, which is presumably caused by chemotactic factors such as C5a released when antigonococcal antibody binds complement, may become more profuse and blood tinged as the infection progresses. Some strains of gonorrhea have a propensity to cause asymptomatic or minimally symptomatic infection with negative Gram stain.

Patients with asymptomatic or minimally symptomatic disease may serve as reservoirs for the infection, evading treatment for prolonged periods.[10] At one time, only females were thought to have asymptomatic gonorrhea, but now it is known that males may be asymptomatic carriers as well.[11]

In the era before antimicrobials, gonococci occasionally spread to the epididymis, causing unilateral epididymitis; the prevalence was 5% or more in patients in some studies. Currently, epididymitis occurs in <1% of males with gonorrhea. Urethral stricture after repeated attacks and sterility after epididymitis are now rare complications of gonococcal infection owing to the effectiveness of antibiotics.

DIAGNOSIS: MALES

Case 72-1, Question 3: Intracellular gram-negative diplococci were seen on the Gram stain of D.S.'s urethral exudate. Is any further diagnostic testing required?

Demonstration of intracellular gram-negative diplococci in the gram-stained exudate confirms the diagnosis in symptomatic males. Until recently, some experts recommended that cultures be reserved for individuals with negative Gram stain finding of urethral exudate. However, today, cultures are recommended for all patients to permit isolation and testing of the bacteria for antibiotic susceptibility. Cultures usually are performed on Thayer–Martin medium, an

enriched chocolate agar to which vancomycin, colistimethate, and nystatin have been added. Cultures from the throat should be obtained if D.S. were exposed by cunnilingus to the prostitute. In D.S.'s case, symptomatic urethritis with the presence of polymorphonuclear leukocytes (PMNs) with intracellular gram-negative diplococci on a Gram stain of the urethral specimen does not require further testing and is sufficient to establish a diagnosis of gonorrhea. See Case 72-1, Question 5, for situations where further testing may be needed with a nucleic acid amplification test (NAAT).

SIGNS AND SYMPTOMS: FEMALES

Case 72-1, Question 4: C.S., D.S.'s wife, is asymptomatic. What symptoms would be consistent with gonorrhea in C.S.? Do the symptoms differ because she is pregnant? What is the natural course of gonorrhea in females if left untreated?

Urogenital gonococcal infections in females are commonly asymptomatic. Because the endocervical canal is the primary site of urogenital gonococcal infection in females, the most common symptom is vaginal discharge. Many females infected with gonorrhea have abnormalities of the cervix, including purulent or mucopurulent endocervical discharge, erythema, friability, and edema of the zone of ectopy.[9] The incubation period for urogenital gonorrhea in females is variable.[12] PID is a serious complication in 10% to 20% of females with acute gonococcal infection and can lead to infertility and chronic pelvic pain.[2,9] The assessment of signs and symptoms in females with gonorrhea often is confounded by nonspecific signs and symptoms and a high prevalence of coexisting infection, especially with *Chlamydia trachomatis* or *Trichomonas vaginalis.*

Although lower genital tract symptoms in females may disappear, they remain carriers of *N. gonorrhoeae* and should be treated. Complications of urogenital gonorrhea in pregnancy include spontaneous abortion, premature rupture of the fetal membranes, premature delivery, and acute chorioamnionitis.[13–15] Other

complications include gonococcal arthritis (see Case 72-4, Question 1), conjunctivitis, and ophthalmia neonatorum in the newborn.[16] For these reasons, it is critical that C.S. be worked up thoroughly for gonorrhea.

DIAGNOSIS: FEMALES

Case 72-1, Question 5: How should gonorrhea be ruled out in C.S.?

NAATs, such as the polymerase chain reaction (PCR), are recommended for the detection of *N. gonorrhoeae* in males and females from urogenital sites regardless of whether symptoms are present.[17] Although NAATs are not FDA approved for the detection of *N. gonorrhoeae* at nonurogenital (or extragenital) sites, laboratories should meet Clinical Laboratory Improvement Amendments (CLIA) requirements and performance specifications for use with rectal and oropharyngeal specimens; NAATs are the recommended detection method for rectal and orophyaryngeal specimens. Although culture for *N. gonorrhoeae* is not ideal for routine diagnosis, cultures should be performed for isolation and identification, antibiotic susceptibility, and resistance surveillance. Cultures should also be performed in cases of suspected treatment failures, defined as those that have received CDC-recommended treatment and subsequently have a positive *N. gonorrhoeae* test result 7 days after treatment, and did not engage in sexual activity during those 7 days.[17] In C.S., a NAAT from the anal specimen also could be performed because the rectum can serve as a reservoir for gonococci.

TREATMENT

Case 72-1, Question 6: What are the various drug regimens used for uncomplicated gonorrhea?

The CDC recommendations are summarized in **Table 72-1**. The CDC recommends a single dose of intramuscular (IM) ceftriaxone

500 mg as the preferred treatment of gonorrhea.[18] Cefixime 800 mg orally (PO) as a single dose is no longer recommended as a first-line treatment by the CDC, but as an alternative option when ceftriaxone cannot be used. Many strains of *N. gonorrhoeae* exhibit plasmid-mediated resistance to penicillin and tetracycline (penicillinase-producing *Neisseria gonorrhoeae* [PPNG] and/or tetracycline-resistant *Neisseria gonorrhoeae* [TRNG], respectively; **Fig. 72-2**). In addition, significant levels of chromosomally mediated resistance to penicillin, tetracycline, and cefoxitin have been reported.[2]

Table 72-1
CDC Recommendations for Treatment of Uncomplicated Gonorrhea

Presentation	Drugs of Choice (% Cured)	Dosage	Alternative Regimens
Urethritis, cervicitis, rectal[a]	Ceftriaxone (99.2)	500 mg IM once	Cephalosporin single-dose regimens[b]
Pharyngeal[a]	Ceftriaxone (98.9)	500 mg IM once	

IM, intramuscularly: PO, orally.

[a]Because a high percentage of patients with gonorrhea have coexisting *Chlamydia trachomatis* infections, a course of doxycycline 100 mg twice daily for 7 days should be given with recommended gonorrhea treatment if chlamydia has not been excluded.

[b]Additional cephalosporin regimens include cefixime 800 mg orally (PO), ceftizoxime 500 mg intramuscularly (IM), cefoxitin 2 g IM (administered with probenecid 1 g PO), and cefotaxime 500 mg IM.

Source: Adapted from Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4): 1–187. doi:10.15585/mmwr.rr7004a1.

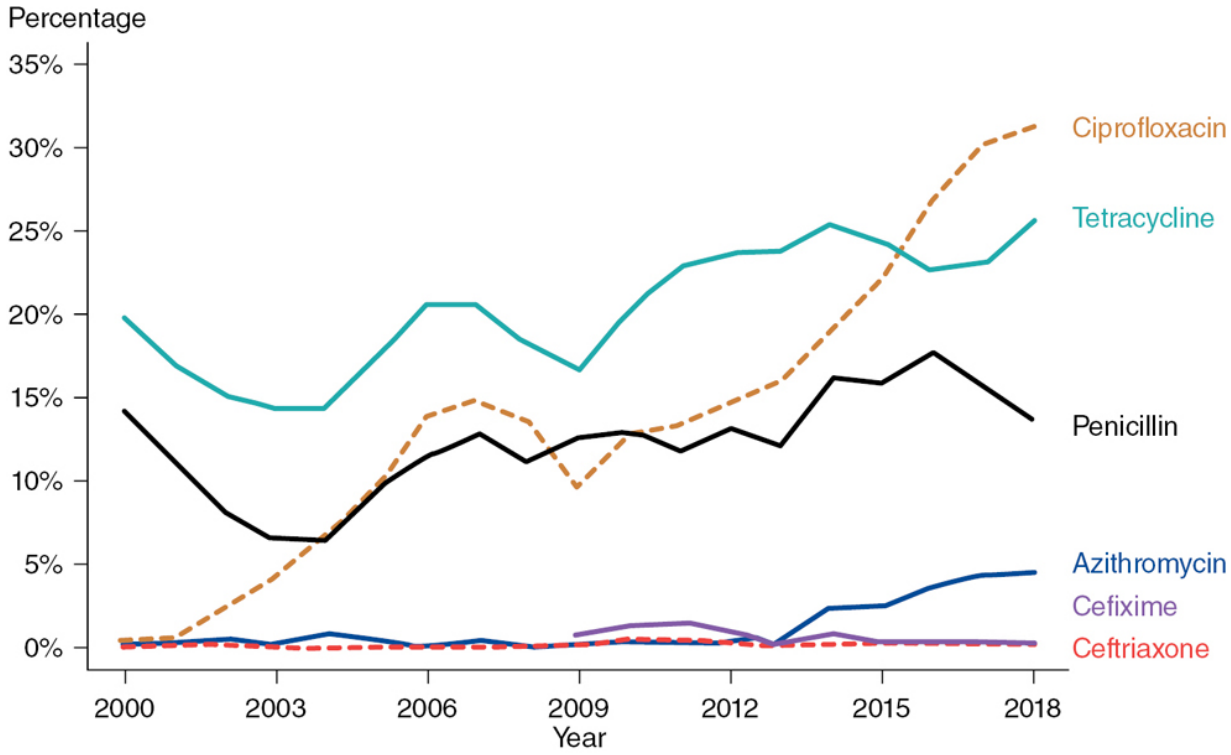

Figure 72-2 Prevalence of minimum inhibitory concentrations (MICs) of common antibiotics to *Neisseria gonorrhoeae*. In 2018, 31.2% of isolates collected from the Gonococcal Isolate Surveillance Project (GISP) sites were resistant to ciprofloxacin, 25.6% to tetracycline, and 13.7% to penicillin. (Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats18/figures/31.htm.)

Failure of penicillin to eradicate the gonococcus can be the result of plasmid (eg, PPNG) or chromosomally mediated resistant *Neisseria gonorrhoeae* (CMRNG) antibiotic resistance. PPNG contain plasmids that determine the production of lactamase, an enzyme that hydrolyzes the lactam ring of penicillin G or ampicillin. Chromosomally mediated resistance does not involve β-lactamase production and often is associated with increased resistance to other β-lactams. The clinical significance of CMRNG is questionable because serum levels of approved antibiotics are achieved far above the minimum inhibitory concentration, such that treatment failure is unlikely. However, to date, CMRNG remain largely susceptible to

ceftriaxone. High-level tetracycline resistance is defined by gonococci that carry plasmid-encoded resistance to 16 g/mL or more of tetracycline. These strains are known as *TRNG*. Although not of major concern in the United States, development of resistance to alternative therapies is a continuing concern.

Quinolone-resistant *Neisseria gonorrhoeae* (QRNG) was first reported in 1990 and was reported to be 0.2% of isolates in the continental United States.[4],[19] In 2007, increasing emergence of fluoroquinolone-resistant *N. gonorrhoeae* in the United States prompted the CDC to cease recommending fluoroquinolones for treatment of gonorrhea.[20] Resistance to fluoroquinolones is associated with mutations of *GyrA* and is commonly identified in strains that produce β-lactamase and strains exhibiting chromosomally mediated resistance to penicillin and tetracycline.[21],[22] *N. gonorrhoeae* strains may therefore exhibit decreased susceptibility or complete resistance to the recommended dose of quinolones, and the clinical importance of strains with decreased susceptibility is unknown.[23]

Owing to the emergence of high levels of resistance to these antibiotics, the CDC no longer recommends the use of fluoroquinolones, tetracycline, or penicillin for the treatment of gonorrhea.[2],[20] Because a high percentage of patients with gonorrhea are also coinfected with *C. trachomatis*, a 7-day course of doxycycline is recommended to be taken concurrently when chlamydia infection has not been excluded (see Case 72-1, Question 7). Since 2020, the CDC no longer recommends presumptive *Chlamydia trachomatis* treatment with azithromycin due to increasing azithromycin resistance for gonorrhea and other organisms.[18],[24]

The antibiotic resistance profile for gonorrhea is defined as fluoroquinolone (ciprofloxacin): minimum inhibitory concentration (MIC) ≥1.0 μg/mL; penicillin: MIC ≥2.0 μg/mL or β-lactamase positive; tetracycline: MIC ≥0 μg/mL. Elevated MICs = azithromycin: MIC ≥1.0 μg/mL (2000–2004), ≥2.0 μg/mL (2005–2018); ceftriaxone: MIC ≥0.125 μg/mL; cefixime: MIC ≥0.25 μg/mL.

IM spectinomycin, which traditionally had been used in individuals who could not tolerate fluoroquinolones or cephalosporins, is still

unavailable from the manufacturer.[25] Although limited data exist for the treatment of gonorrhea in patients with cephalosporin or immunoglobulin (Ig)E-mediated penicillin allergy, potential alternative treatments are a single dose of gentamicin 240 mg IM plus azithromycin 2 g PO.[18],[26] Individuals who have either penicillin or cephalosporin allergies should be desensitized to cephalosporins before treatment begins.[27]

Ceftriaxone and other cephalosporins

Ceftriaxone, a third-generation cephalosporin, is given as a single, small-volume IM injection that eradicates gonorrhea at all anatomic sites and is also safe in pregnancy (U.S. Food and Drug Administration [FDA] pregnancy category B). Ceftriaxone is ineffective against *C. trachomatis* and in the prevention of postgonococcal urethritis, whereas ofloxacin and levofloxacin for 7 days have similar efficacy to doxycycline.[15] Other injectable cephalosporins (notably ceftizoxime, cefoxitin, and cefotaxime) have been found to be safe and highly effective, but do not offer any advantage over ceftriaxone for urogenital infections, and their efficacy in pharyngeal infections is not as well established. A single oral dose of cefixime is also effective in curing 92.3% of uncomplicated urogenital and anorectal gonorrhea infections.[2],[18] However, the CDC no longer recommends cefixime as a first-line regimen owing to recent concerns about declining cefixime susceptibility among urethral *N. gonorrhoeae* isolates in the United States.[2],[18] Other oral cephalosporins such as cefpodoxime and cefuroxime are not recommended owing to inferior efficacy and less favorable pharmacodynamics; however, they are FDA approved to treat uncomplicated *N. gonorrhoeae*. Although ceftriaxone is used as a first-line regimen, there is increasing concern for resistance. In 2018, 0.2% of isolates had elevated ceftriaxone MIC, and MICs have fluctuated between 0.1% and 0.4% between 2009 and 2018.[6] These concerns of ceftriaxone resistance prompted the CDC in 2020 to increase the ceftriaxone dose for uncomplicated gonorrhea from 250 to 500 mg.[18]

Prescribing patterns

The CDC's 2018 Sexually Transmitted Disease Surveillance Program observed that 96.5% of treated patients received ceftriaxone. The number of those treated with cefixime decreased from 0.3% in 2015 to 0.1% in 2018. This decrease in cefixime use was expected as CDC recommendations were to avoid the use of cefixime at any dose as first-line therapy.[18] Treatment with gentamicin 240 mg increased from 0.2% in 2015 to 1.4% in 2018. Prescribed treatment for gonorrhea, in order of most frequently used, was ceftriaxone, gentamicin, azithromycin, and cefixime (**Fig. 72-3**).

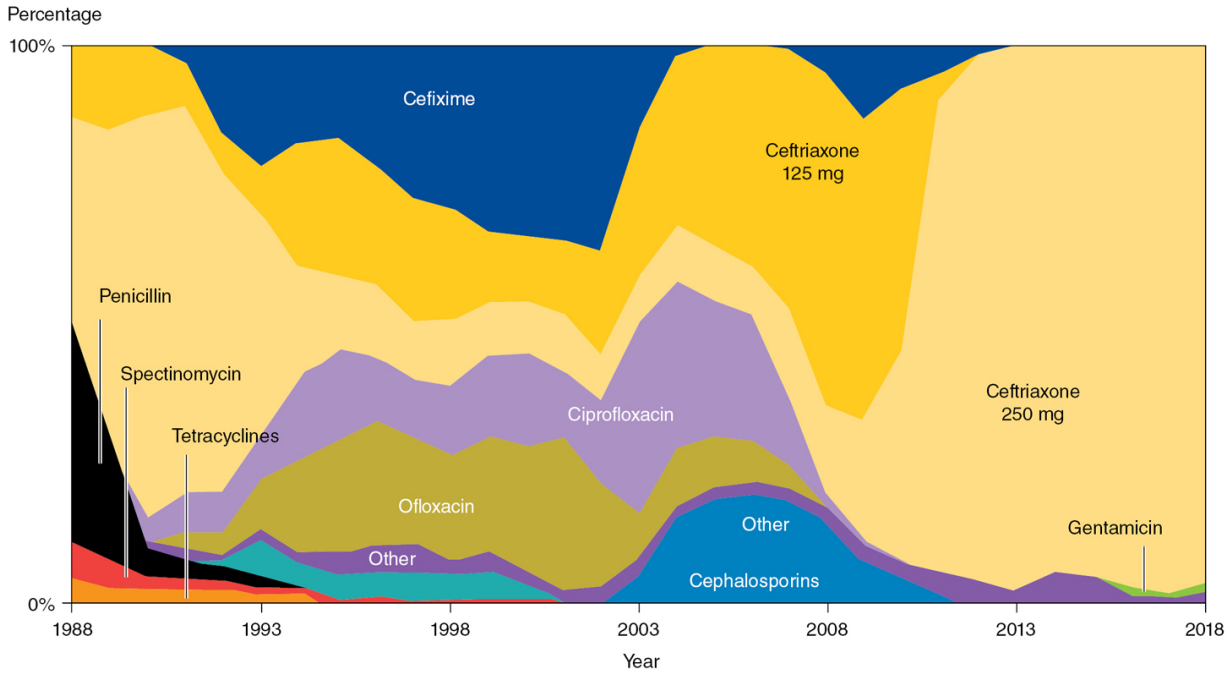

Figure 72-3 Area graph showing the distribution of primary antimicrobial drug used to treat gonorrhea among Gonococcal Isolate Surveillance Project (GISP) participants from 1988 to 2018. (From Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats18/figures/33.htm.)

Case 72-1, Question 7: How should D.S.'s urethritis be treated? Because C.S. is totally asymptomatic and the results of her cultures are pending, should she be treated empirically? If so, what drug(s) would you recommend?

Because D.S. has gonococcal infection limited to the urethra (uncomplicated), a few treatment regimens are possible, as outlined in Case 72-1, Question 6. Ceftriaxone is the preferred treatment, with cefixime as an alternative, only if ceftriaxone is not available. Quinolones should be avoided because of increased resistance in *N. gonorrhoeae* and because D.S.'s infection was likely obtained in the Philippines, where quinolone resistance occurs in more than half of all isolates.[20],[28] Patients with gonorrhea may also be coinfected with chlamydia, and therefore presumptive cotreatment with doxycycline 100 mg PO twice daily for 7 days could be initiated if coinfection is suspected.[29],[30]

Sexual partners

C.S. also should be treated even though she appears asymptomatic. All partners who have had sexual exposure to patients with gonorrhea within 60 days should be treated. If the patient has not been sexually active for 60 days, the most recent sexual partner should be treated. This is especially true when the partner is pregnant because gonorrhea during pregnancy is associated with chorioamnionitis and prematurity, as well as neonatal infection. Pregnant females can be treated safely with cephalosporins and azithromycin for gonorrhea and chlamydia. Doxycycline should be avoided during pregnancy.

Follow-up

Case 72-1, Question 8: How does one determine whether the drug therapy of gonorrhea has been effective in D.S. and C.S.?

If recommended therapies are used for the treatment of uncomplicated gonorrhea, a test of cure is not necessary for either C.S. or D.S. because cure rates are close to 100%.[2] However, a test of cure should be done 7 to 14 days after treatment in those with pharyngeal infection using culture or NAATs regardless of treatment regimen.[2],[18] If symptoms persist in D.S., who was treated with

ceftriaxone, cultures should be done to determine antibiotic susceptibility, and to rule out other causes of urethritis.

Anorectal and Pharyngeal Gonorrhea

EPIDEMIOLOGY

CASE 72-2

Question 1: M.B. is a 24-year-old, sexually active MSM with a 2-month history of perianal itching, painful defecation, constipation, a bloody mucoid rectal discharge, and a sore throat. Sigmoidoscopy revealed rectal mucosal inflammation but no apparent ulcers or fissures. Stool examination for parasites returned a negative result and a Venereal Disease Research Laboratory (VDRL) test result was nonreactive. Both rectal and pharyngeal culture results revealed *N. gonorrhoeae.*

How does gonorrhea infection in MSM compare with gonorrhea infection in MSW?

Rectal infection occurs rarely in strictly MSW, whereas in the MSM population, anorectal (25%) and pharyngeal (10%–25%) gonococcal infections occur more often.[9,31] CDC data in 2018 from STD clinics saw a median positivity of 14.8% rectal and 12.9% pharyngeal gonorrhea among MSM.[6] Because pharyngeal[31,32] and anorectal gonococcal infections are often asymptomatic, a large reservoir of carriers in the homosexual male population may exist, and annual screening should be done if they have engaged in receptive oral or anal intercourse in the preceding year. By comparison, very few urethral gonococcal infections are asymptomatic. In addition, data indicate that pharyngeal infections may be an important source of urethral gonorrhea in homosexual males, spread by fellatio.[31,33]

SIGNS AND SYMPTOMS

Case 72-2, Question 2: Are M.B.'s signs and symptoms consistent with gonorrhea?

Rectal gonorrhea produces the syndrome of proctitis with anorectal pain, mucopurulent anorectal discharge, constipation, tenesmus, and anorectal bleeding. The differential diagnosis of proctitis in MSM includes rectal infection with *N. gonorrhoeae, C. trachomatis*, HSV, and syphilis. Proctitis, limited to the distal rectum, should be differentiated from proctocolitis, which is often caused by *Shigella* species, *Campylobacter* species, or *Entamoeba histolytica* in homosexual males. The incidence of rectal gonorrhea and chlamydia has risen dramatically since 1996.[34] Rectal chlamydia is often asymptomatic and observed more often than is gonorrhea, necessitating testing for both pathogens.[35] Although pharyngeal gonorrhea is often asymptomatic, a review of the system and physical exam may reveal a sore throat, pharyngeal exudates, or cervical lymphadenitis.

TREATMENT

Case 72-2, Question 3: How should M.B.'s diagnosis be managed?

The treatment of choice for patients such as M.B. with anorectal or pharyngeal gonorrhea is ceftriaxone 500 mg IM as a single dose (see Table 72-1).[2] Doxycycline should also be given to treat possible coexisting rectal chlamydial infection. Patients such as M.B. with either anorectal or pharyngeal gonorrhea should be advised to avoid further unprotected sexual activity and should be counseled and tested for infection with HIV.

Case 72-2, Question 4: What are alternative regimens for patients with isolated anal or pharyngeal gonorrhea?

Patients with anorectal gonorrhea alone should be treated with ceftriaxone. Oral cefixime is a recommended alternative but should not be used as a first-line agent. As with urogenital infections, alternative regimens for isolated anorectal infection include a single-dose cephalosporin regimen such as ceftizoxime. Because

spectinomycin is unavailable, patients with anorectal gonorrhea who are allergic to penicillin or cephalosporins should be desensitized before treatment is initiated. Patients with gonococcal infections of the pharynx should be treated with ceftriaxone; however, infections of this nature are more difficult to eradicate than are infections at urogenital and anorectal sites. Treatment for gonorrheal infections at these sites should also include doxycycline for presumptive chlamydial coinfection if it has not been excluded.[2,18]

PREVENTION

CASE 72-2, QUESTION 5: What measures have been used to prevent the sexual transmission of infection?

Condoms, when used properly, seem to provide a high degree of protection against the acquisition and transmission of STDs.[2,36] Previous studies indicated that the use of the spermicide nonoxynol-9 had activity against gonorrhea and chlamydia; however, in light of recent evidence suggesting that nonoxynol-9 might actually increase the risk of acquiring HIV and other STDs, the FDA currently requires manufacturers of nonoxynol-9 products to include a warning statement on the product's label that it does not protect against HIV or other STDs.[15,37] Topical antibacterial agents, urinating, and washing after intercourse are of little value in preventing the transmission of STDs. Douching may increase the risk of other STDs such as trichomoniasis.[38]

The prophylactic administration of antibiotics immediately before or soon after sexual intercourse is not recommended owing to increased costs and antimicrobial resistance. Use of rapid, specific tests and empiric symptomatic management should be used to enhance detection and treatment of gonorrhea.

PELVIC INFLAMMATORY DISEASE

The term *pelvic inflammatory disease (PID)* refers to a variety of inflammatory disorders of the upper female reproductive tract. This term does not denote the primary infection site (the fallopian tubes) nor the causative microorganisms. PID also has been used to connote an infection that occurs acutely when either vaginal or cervical microorganisms traverse the sterile endometrium and ascend to the fallopian tubes. Acute salpingitis also may be used to describe an acute infection of the fallopian tubes. Therefore, the terms *PID* and *salpingitis* are used interchangeably in this discussion to denote an acute infection involving the fallopian tubes.

PID affects ~2.5 million females annually in the United States.[39] However, the National Disease and Therapeutic Index (NDTI) estimates that from 2007 to 2016, the number of initial visits to physicians for PID for females ages 15 to 44 years decreased 38.3% from 146,000 to 90,000 visits. Many cases of acute PID occur by sexual transmission, especially in females ages 16 to 24 years who are more likely to have multiple sexual partners.[40] Risk factors for the development of PID include unprotected sexual intercourse before age 15, douching, bacterial vaginosis (BV), sex while menstruating, and smoking.[41] It is unclear whether an intrauterine device (IUD) increases the risk of PID, but it may be prudent to avoid placement when the patient has chlamydial or gonococcal cervicitis.[42] Two-thirds of PID cases resulting in infertility are asymptomatic, and up to one-third are incorrectly diagnosed owing to low specificity of diagnostic techniques. In the United States, infertility occurs in about 12.1% of females after the first episode of PID.[43] The estimated costs for treatment of PID and its sequelae exceed $4.2 billion annually.[44]

Etiology

Most cases of PID are caused by *C. trachomatis* and *N. gonorrhoeae.* Some microorganisms that make up the vaginal flora are also associated with PID including *Gardnerella vaginalis, Haemophilus influenzae*, and *Streptococcus agalactiae. M. hominis,*

Ureaplasma urealyticum, M. genitalium, and cytomegalovirus (CMV) have also been associated with PID, but a causative role is unclear.[15] Cases of PID are also associated with polymicrobial infection, BV, and anaerobic gram-negative rods.[45] Facultative enteric gram-negative bacilli and a variety of anaerobic bacteria have also been isolated from the upper genital tract of up to 70% of females with acute PID.[45] Females diagnosed with acute PID should be tested for *C. trachomatis* and *N. gonorrhoeae* using NAAT and screened for HIV.[2]

Signs and Symptoms

The variations in presentation and nonspecific signs and symptoms of PID make it a complex disease to diagnose. The onset of abdominal pain attributable to PID caused by either gonococci or chlamydia often occurs soon after the menstrual period. Additional symptoms, if present, are often non-specific, which can create a delay in or failure of diagnosis. Vaginal discharge, menorrhagia, dysuria, and dyspareunia are commonly associated with PID. Pelvic examination findings include cervical motion tenderness, uterine tenderness, or adnexal tenderness. Temperatures >101 °F (38.33 °C), abnormal cervical or vaginal mucopurulent discharge, white blood cells (WBCs) on saline microscopy of vaginal secretions, elevated erythrocyte sedimentation rate, elevated C-reactive protein, or laboratory documentation of cervical infection with *N. gonorrhoeae or C. trachomatis* support a diagnosis of PID.[2] Clinical diagnosis has a sensitivity for PID of 65% to 90%, whereas laparoscopy and a newer technique, transvaginal Doppler ultrasound, are 100% specific, resulting in the combination of laparoscopy and clinical impression serving as the gold standard.[2,46,47] Unfortunately, laparoscopy and Doppler ultrasound are costly and often not readily available for acute cases and they are not diagnostic for endometritis; thus, clinical impression is critical. A key to reducing the incidence of PID may be through active screening of *Chlamydia* in young, sexually active females.[48,49]

Clinical Sequelae

An abscess may form in the pelvic or abdominal cavity and or one or both fallopian tubes. Chronic abdominal pain develops in 18% of females with PID and may be the result of pelvic adhesions surrounding the tubes and ovaries. After a single episode of PID, tubal occlusion and fibrosis secondary to fallopian tube inflammation (salpingitis) result in 12% infertility, 25% infertility after two episodes, and 50% infertility after three or more episodes.[43] Other sequelae include ectopic pregnancy (9%) and chronic pelvic pain (18%).[50] The risk of ectopic pregnancy is increased approximately eightfold after one or more episodes of PID.

Diagnosis and Treatment

CASE 72-3

Question 1: H.C., a 19-year-old, sexually active female, presents with mild dysuria, a purulent vaginal discharge, fever, and moderately severe, bilateral, lower abdominal pain of 3 days duration. Examination confirms uterine and adnexal tenderness, a purulent cervical exudate, and a temperature of 102.20 °F (39 °C). Laboratory examinations show a nonreactive VDRL and negative urinalysis. A pregnancy test performed returned a negative result. The peripheral WBC count was mildly elevated (11,000/μL), with 70% PMNs.

Does H.C. have PID? How should she be treated?

Although fever and leukocytosis are often absent in mild or subacute PID, these findings in a female with uterine and adnexal tenderness with cervical exudate increases the likelihood of acute PID. Recommended treatment regimens for PID are listed in **Table 72-2** and should be initiated immediately after diagnosis of PID to prevent clinical sequelae; confirmation of the actual pathogen rarely takes place. Patients such as H.C. with mild-to-moderate PID can be hospitalized and treated with parenteral antibiotics; however, clinical efficacy and overall outcomes are equal between parenteral and oral therapy, and H.C. could also be treated on an outpatient basis. For inpatient treatment, the CDC recommends either intravenous (IV)

cefotetan 2 g every 12 hours or IV cefoxitin 2 g every 6 hours for at least 24 hours beyond the first signs of clinical improvement along with doxycycline 100 mg every 12 hours. Once clinical improvement is noted, parenteral therapy may be discontinued, and PO doxycycline 100 mg every 12 hours can continue to complete 14 days of therapy. For outpatient treatment, the CDC guidelines recommend either IM ceftriaxone 250 mg as a single dose or IM cefoxitin 2 g as a single dose (with probenecid 1 g PO for one dose) plus PO doxycycline 100 mg twice a day for 14 days with or without PO metronidazole 500 mg twice daily for 14 days.[2] A tetracycline derivative or an alternative agent that is active against *C. trachomatis* should be included in the treatment of PID; however, monotherapy with a tetracycline is not recommended because of the lack of activity against gram-negative aerobic and anaerobic organisms and *N. gonorrhoeae.* The addition of metronidazole, which covers anaerobic bacteria, should also be considered; anaerobes have been isolated from the upper reproductive tract of females with PID and may cause tubal and epithelial destruction.[2,51] Metronidazole is widely used by clinicians because BV is frequently associated with PID.[2] Fluoroquinolones such as levofloxacin and ofloxacin are no longer recommended for the treatment of PID because of the increase in the prevalence of QRNG in the United States.[20]

Table 72-2
Antimicrobial Regimens Recommended by the CDC for Treatment of Acute Pelvic Inflammatory Disease

Treatment Setting, Drugs, Schedule	Advantage	Disadvantage	Clinical Considerations
Inpatient (Parenteral) Therapy			
Regimen A			
Cefotetan 2 g IV every 12 hours *or* cefoxitin 2 g IV every 6 hours *plus* doxycycline 100 mg IV or PO[a] every 12 hours Continue doxycycline (100 mg PO twice daily) after discharge to complete 14 days of therapy.	Optimal coverage of *Neisseria gonorrhoeae* (including resistant strains) and *Chlamydia trachomatis*	Possible suboptimal anaerobic coverage	Penicillin-allergic patients also may be allergic to cephalosporins; doxycycline use in pregnant patients may cause reversible inhibition of skeletal growth in the fetus and discoloration of teeth in young children.
Regimen B			
Clindamycin 900 mg IV every 8 hours *plus* gentamicin loading dose IV or IM (2 mg/kg) followed by a maintenance dose of 1.5 mg/kg every 8 hours[b]	Optimal coverage of anaerobes and gram-negative enteric rods	Possible suboptimal coverage of *N. gonorrhoeae* and *C. trachomatis*	Patients with decreased renal function may not be good candidates for aminoglycoside treatment or may need a dosage adjustment.
Alternative Regimen			
Ampicillin/sulbactam 3 g IV every 6 hours *plus* doxycycline 100 mg PO or IV every 12 hours	Optimal coverage of *N. gonorrhoeae* and *C. trachomatis*	Inadequate coverage of anaerobes necessitates the use of metronidazole or ampicillin/sulbactam.	Not appropriate in pregnancy or in young children
Outpatient (Intramuscular or Oral) Therapy[c]			
Ceftriaxone 500 mg IM in a single dose *plus* doxycycline 100 mg PO twice daily for 14 days *with* metronidazole 500 mg PO twice daily for 14 days *or* Cefoxitin 2 g IM in a single dose and probenecid, 1 g PO administered concurrently in a single dose *plus* doxycycline 100 mg PO twice daily for 14 days *with* metronidazole 500 mg PO twice daily for 14 days *or* Other parenteral third-generation cephalosporins (eg, ceftizoxime or cefotaxime) *plus* doxycycline 100 mg PO twice daily for 14 days *with* metronidazole 500 mg PO twice daily for 14 days	Good to excellent coverage of *N. gonorrhoeae* and optimal coverage of *C. trachomatis*	Possible suboptimal anaerobic coverage necessitating the addition of metronidazole	Optimal cephalosporin is unclear; more complicated regimen requiring a combination of parenteral and oral therapies

CDC, Centers for Disease Control and Prevention; IM, intramuscular; IV, intravenous; PID, pelvic quality disease; PO, orally.

[a]Considering the oral bioavailability of doxycycline, oral (PO) therapy should be preferentially used over intravenous (IV).

[b]Single daily dosing (3–5 mg/kg) may be substituted.

[c]Consider for mild-to-moderate acute PID.

Source: Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1.

Both oral and IV doxycycline have similar bioavailability; therefore, doxycycline should be given PO whenever possible.[2] Substantial clinical improvement is usually seen within 3 days of initiation of therapy. Clindamycin plus gentamicin can be used alternatively in penicillin-allergic and pregnant females.[2] Because H.C. is sexually active, any sexual partners within the previous 60 days (or if >60 days, then the most recent sexual partner) should be empirically treated because of the risk of gonococcal or chlamydial urethritis as well as to reduce the risk of reinfection.[2]

COMPLICATED GONORRHEA

Disseminated Gonococcal Infection

SIGNS AND SYMPTOMS

CASE 72-4

QUESTION 1: S.P., a 28-year-old, sexually active female, was seen for stiffness and pain of the right wrist and left ankle and fever (100.40 °F [38 °C]). On physical examination, the knee and wrist joints were found to be hot, red, and swollen; papules and pustular lesions were observed on S.P.'s legs and forearms. A latex fixation test result for rheumatoid factor was negative. A tap of the right knee yielded an effusion with a WBC count of 34,000/μL (80% PMNs). Culture results of the skin lesions were negative, but *N. gonorrhoeae* was isolated from the throat, cervix, blood, and synovial fluid. A chest radiograph, echocardiogram, and electrocardiogram findings all were normal, and no murmur could be appreciated.

What do you make of S.P.'s clinical presentation?

S.P.'s signs, symptoms, and laboratory findings are consistent with gonococcal bacteremia, which today occurs in <1% of patients with gonorrhea. The most common manifestation of gonococcemia is the gonococcal arthritis–dermatitis syndrome or DGI exhibited by S.P. Symptoms include fever, occasional chills, a mild tenosynovitis of the

small joints, and skin lesions; the latter, primarily involving the distal extremities, are petechial, papular, pustular, and hemorrhagic in appearance.[2]

Diagnosis of DGI is made by NAAT or culture of specimen from routine sites of gonococcal infections (eg, urethra, cervix, pharynx, and rectum), as well as culture from disseminated sites of infection (eg, synovial fluid, blood, skin, and CNS). However, blood culture results are positive in only 33% of DGI cases, even when culture samples are obtained early in the course of the infection.[15] The low positive yield from blood cultures may be attributable to the low inoculum or intermittent bacteremic period.

TREATMENT

Case 72-4, Question 2: How should S.P. be managed? How quickly will she respond to therapy?

Patients such as S.P. with gonococcal arthritis and bacteremia should be hospitalized for treatment with ceftriaxone 1 g IV or IM daily until substantial clinical improvement is sustained for 24 to 48 hours, at which time therapy may be switched to an oral agent guided by antimicrobial susceptibility for a total treatment course of at least 7 days (**Table 72-3**).[2] Initiation of treatment should also include doxycycline 100 mg twice daily for 7 days. Symptoms and signs of tenosynovitis should be improved markedly within 48 hours. Septic gonococcal arthritis with purulent synovial fluid may require repeated aspiration and resolves more slowly.

Table 72-3
Treatment of Disseminated Gonococcal Infection[a] (No Penicillin Allergy)

No Penicillin Allergy
Parenteral
Recommended[b]: Ceftriaxone 1 g IV or IM every 24 hours

Alternative[b]: Cefotaxime 1 g IV Q 8 hours or ceftizoxime 1 g IV Q 8 hours
Oral[c]: Cefixime 400 mg PO twice daily

IM, intramuscular; IV, intravenous; PO, orally; Q, every.

[a]Parenteral treatment should be continued for 24 to 48 hours beyond clinical improvement.

[b]Doxycycline 100 mg twice daily for 7 days.

[c]Treat for 7 days after switching from parenteral therapy.

Source: Adapted from Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1.

Treatment of Gonococcal Endocarditis and Meningitis

Case 72-4, Question 3: How should gonococcal endocarditis and meningitis be treated?

Gonococcal endocarditis and meningitis, occurring in only 1% to 3% of DGIs, require high-dose IV therapy such as ceftriaxone (1–2 g IV every 12–24 hours) for 10 to 14 days in the case of meningitis and for at least 4 weeks in the case of endocarditis.[2] As with other gonococcal infections, a single dose of azithromycin 1 g PO should be given.

Neonatal Disseminated Gonococcal Infection: Treatment

Case 72-4, Question 4: How should neonatal DGI and meningitis be managed?

Neonatal DGI and meningitis can be treated with either ceftriaxone 25 to 50 mg/kg (IV or IM) daily or cefotaxime 25 mg/kg (IV or IM) every 12 hours. Treatment is for 7 days for DGI; however, meningitis

requires 10 to 14 days of treatment.[2] Although ceftriaxone is also effective in the treatment of neonatal DGI and meningitis, cefotaxime is considered a safer choice in the neonatal population.

CHLAMYDIA TRACHOMATIS

The rate of reported *Chlamydia* infections has climbed steadily each year since the 1980s and is the most commonly reported STD in the United States. From 2000 to 2018, the reported rate of chlamydial infections increased from 254.1 to 539.9 cases per 100,000 individuals.[6] This increase may be attributable to the increased development and use of more sensitive screening tests, improved national reporting efforts, or a true increase in the incidence of disease.[15] Females are three times more likely than are males to be infected with *Chlamydia*—692.7 cases versus 380.6 cases per 100,000 individuals, respectively, in 2018. However, from 2014 to 2018, the infection rate among males increased 37.8% compared with 11.4% in females. The highest rate of infection is in females 20 to 24 years (4064.6 cases per 100,000 females) and in males 20 to 24 years (1784.5 cases per 100,000 males).[6] If left untreated, chlamydial infection in females can lead to serious sequelae such as PID, ectopic pregnancy, and infertility. Asymptomatic infection is also observed in both males and females; however, routine screening is recommended for sexually active females up to 25 years of age and older females with risk factors for infection (eg, multiple sexual partners or having a new sexual partner). Screening sexually active males for *C. trachomatis* can be considered in settings or populations with a high prevalence of the infection (eg, MSM population).[2]

C. trachomatis, an obligate intracellular bacterium, can be diagnosed by culture, direct immunofluorescence assay (DFA), enzyme immunoassay (EIA), or NAAT of endocervical or male urethral swabs.[15] However, *C. trachomatis* is a difficult organism to demonstrate in clinical specimens because cell culture techniques

are not readily available to the practitioner. Because few practitioners have access to facilities for isolation of *C. trachomatis,* most chlamydial infections are diagnosed and treated based on clinical impression and laboratory techniques. NAATs are recommended for detecting *C. trachomatis* because it is the most sensitive nonculture diagnostic test method. Ligase chain reaction and PCR are two NAATs with wide commercial availability, are relatively simple to use, can be performed using urine or genital swab specimens, and are more sensitive than are non-NAATs.[16] NAATs are ~20% to 35% more sensitive than are EIAs and DFAs, and they are the recommended test method for the detection of *C. trachomatis* in patients with and without symptoms.[2,17] A test of cure is not necessary unless patient adherence is questionable, symptoms persist, or reinfection is suspected. Repeat testing with NAATs <3 weeks after initiation of treatment is not recommended because false-negative results may occur as a result of undetectable *C. trachomatis* organisms. Moreover, false positives may occur with repeat NAATs with the continued excretion of dead organisms.

A variety of clinical syndromes are caused by *C. trachomatis,* including cervicitis, urethritis, bartholinitis, endometritis, salpingitis, and perihepatitis in females, and urethritis, epididymitis, prostatitis, proctitis, and Reiter syndrome in males.[15] The spectrum of chlamydial infections closely resembles those caused by gonococcus, which is why many patients presenting with these syndromes are treated with drugs effective against both organisms.

There is controversy over how *C. trachomatis* is cultured and what the in vitro results mean clinically, especially in the 10% to 15% of cases that fail treatment.[52] The CDC thus uses cure rates instead of microbial susceptibilities to make treatment recommendations. Only azithromycin and doxycycline have 97% and 98% cure rates, respectively.[2,53] Alternatives include erythromycin, ofloxacin, and levofloxacin. Other quinolones should not be used because they have not been evaluated adequately or are not reliably effective.[2]

Nongonococcal Urethritis

ETIOLOGY

CASE 72-5

QUESTION 1: T.K., a 26-year-old, sexually active male, presents with mild dysuria and a mucoid urethral discharge beginning 15 days after his last intercourse. He has no fever, lymphadenopathy, penile lesions, or hematuria. A Gram stain smear of an anterior urethral specimen showed 20 PMNs per oil immersion (1000) field and no gram-negative diplococci.

What pathogens are associated with nongonococcal urethritis (NGU)?

In the United States, NGU is the most common STD in males.[54],[55] *C. trachomatis* is a frequent cause of NGU, representing 15% to 40% of all cases. Other agents that have been associated with NGU include *M. genitalium*, *T. vaginalis, HSV, and adenovirus*; however, the cause for the majority of NGU cases is unknown.[15] The variety of pathogens and disparity among identification techniques require sound clinical judgment and an algorithmic laboratory testing approach to accurately identify and treat the cause. A NAAT, if available, should be performed to rule out the presence of *C. trachomatis* and *N. gonorrhoeae*.

SIGNS AND SYMPTOMS

CASE 72-5, QUESTION 2: Describe the clinical presentation of a person with NGU. Is T.K.'s presentation consistent with NGU? How can NGU be differentiated from gonococcal urethritis?

T.K.'s presentation is typical. Compared with gonococcal urethritis, NGU typically produces less severe and less frequent dysuria and less penile discharge. Chlamydial urethral infection is completely asymptomatic more often than is gonococcal urethral infection. The incubation period for gonococcal urethritis is 2 to 7 days, whereas the incubation period for NGU is typically 2 to 3 weeks.

Nonetheless, NGU and gonococcal urethritis cannot be reliably differentiated solely on the basis of symptoms and signs. If there is

objective evidence of a urethral discharge (expressed by milking the urethra), a Gram stain of the urethral discharge with ≥2 WBCs per oil immersion field, or urinalysis of first voided urine with positive leukocyte esterase or >10 WBC per high power field, the diagnosis of NGU is made by excluding the presence of *N. gonorrhoeae* by Gram stain and/or culture.

TREATMENT

CASE 72-5, QUESTION 3: How should T.K. be treated?

If *C. trachomatis* cannot be ruled out, therapy with azithromycin 1 g PO for one dose or doxycycline 100 mg PO twice daily for 7 days should be ordered. Compared to doxycycline, *M. genitalium* responds better to azithromycin because doxycycline does not effectively eradicate *M. genitalium*.[2] Azithromycin also has the advantage of a single-dose regimen, which may aid in patient adherence. If adherence is a concern, or the patient is receiving a multidose regimen, all doses of the medication should be dispensed on-site in the clinic, and the first dose should be directly observed. Erythromycin base 500 mg PO four times a day or erythromycin ethylsuccinate 800 mg PO four times a day for 7 days is an alternative CDC-approved regimen. In addition, ofloxacin 300 mg PO twice daily or levofloxacin 500 mg PO every day for 7 days is another alternative, but they offer no significant advantages compared with the previously mentioned agents, may not treat *U. urealyticum* adequately, and are significantly more expensive.[2,56] Ciprofloxacin should be avoided because treatment failures have been reported.[57] Patient counseling should emphasize the need for abstinence from sexual intercourse at least until the prescribed course of therapy has been completed (or 7 days after single-dose therapy) by the patient and his sexual partner(s).[2] There is some indication that the proportion of NGU caused by *C. trachomatis* is declining, potentially being replaced by an increased proportion of *U.*

urealyticum, which is variably cured at 2 weeks by azithromycin (73%) and doxycycline (65%).[58]

Recurrent infection

Case 72-5, Question 4: T.K. was treated with doxycycline 100 mg twice daily for 7 days. He remained asymptomatic for 14 days after completion of his therapy when he again noticed similar symptoms of dysuria and a mucoid urethral discharge. How should T.K.'s recurrent infection be treated?

The major problem encountered in the treatment of NGU is the high rate of recurrent infections. Males receiving treatment should follow up if symptoms persist or recur after completion of therapy. Approximately 20% to 60% of patients experience recurrent or persistent urethritis within 1 to 2 weeks of treatment.[59] The rate of recurrence is highest in patients with idiopathic urethritis, that is, those not infected with *C. trachomatis* or *U. urealyticum.* Recurrence suggests reexposure to an untreated partner, whereas persistent urethritis (without improvement during therapy) suggests the presence of other organisms including *M. genitalium*, *U. urealyticum,* or *T. vaginalis*.[2],[60],[61] NGU that persists or recurs should be retreated with the initial regimen if the patient was not compliant or the sexual partner was not treated. For patients with persistent symptoms who were compliant with the initial regimen and were not reexposed, the CDC recommends using a single 1-g dose of azithromycin if not used for the initial episode or moxifloxacin 400 mg PO daily for 7 days if the patient has failed azithromycin.[2]

Males with acute epididymitis often have a chlamydial or gonococcal infection, particularly if they are younger than age 35 years or have a urethral discharge. *Escherichia coli* and *Pseudomonas* species are common pathogens in homosexual males. In older males, sexually transmitted epididymitis is less common and is more commonly caused by urinary tract instrumentation, surgery, systemic disease, or immune suppression.[2] If testicular tenderness is present with urethritis, and the clinical

impression is consistent with epididymitis caused by *Chlamydia* or gonorrhea, the CDC recommends a single dose of ceftriaxone 250 mg IM plus doxycycline 100 mg PO twice for 10 days. For acute epididymitis caused by enteric organisms or with a negative gonococcal culture or NAAT, ofloxacin 300 mg PO twice daily or levofloxacin 500 mg PO once daily for 10 days may be used.[2,51] In males who practice insertive anal sex, where the most likely cause of acute epididymitis is caused by chlamydia, gonorrhea, and enteric organisms, the CDC recommends ceftriaxone 250 mg IM in a single dose plus levofloxacin 500 mg PO daily or ofloxacin 300 mg PO bid for 10 days.[2]

SEXUAL PARTNERS

Case 72-5, Question 5: A.C., T.K.'s girlfriend, comes into the clinic 3 weeks after T.K.'s last visit. She is worried that she may have a similar infection, although she has no signs or symptoms. What clinical manifestations of chlamydial infections are seen in females? Should A.C. be treated for suspected chlamydial infection?

In the absence of cultures for chlamydia, empirical treatment against chlamydia in females who are sexual partners of males with NGU is recommended. Many partners are asymptomatic, but from 30% to 70% return positive culture results if tested. A.C. should be examined carefully for mucopurulent cervicitis and salpingitis. Although many females with chlamydial infection of the cervix are asymptomatic, up to one-quarter have evidence of mucopurulent discharge.[62] A Gram stain of appropriately collected mucopurulent endocervical discharge from patients with chlamydia infection shows many PMNs and no gonococci.

Regardless of findings, treatment should be initiated with the same azithromycin or doxycycline regimen used for NGU. However, if A.C. is pregnant, tetracyclines and fluoroquinolones should be avoided. Azithromycin 1 g PO as a single dose or amoxicillin 500 mg PO three times a day for 7 days could be used instead. Alternatively, either erythromycin base 500 mg PO four times a day for 7 days,

erythromycin base 250 mg PO four times a day for 14 days, erythromycin ethylsuccinate 800 mg PO four times a day for 7 days, or erythromycin ethylsuccinate 400 mg PO four times a day for 14 days can be used.[2] Erythromycin estolate should be avoided in pregnancy because of the increased risk of hepatotoxicity. Azithromycin is safe and effective during pregnancy.[63],[64] High rates of gastrointestinal (GI) side effects limit the use of erythromycin. In pregnant females, a repeat NAAT is recommended 3 weeks after completion of therapy to ensure therapeutic cure.[2] Coinfection with chlamydia is common in heterosexual males and females with gonorrhea. Therefore, drug regimens effective against both organisms are recommended in patients with gonorrhea to prevent postgonococcal chlamydial morbidity (epididymitis, mucopurulent cervicitis, salpingitis) and to reduce the genital reservoir of *C. trachomatis.*

Lymphogranuloma Venereum

ETIOLOGY AND SIGNS AND SYMPTOMS

CASE 72-6

Question 1: S.F., a 32-year-old male student who reports having sex with females, presents to the STD clinic with pain and swelling in the groin. He reports the appearance of a small ulcer on his penis about 2 weeks ago, which resolved rapidly. On examination, he has a bubo (inflammatory swelling of one or more lymph nodes in the groin) with surrounding erythema on his right side. S.F. also has a fever (102.20 °F [39 °C]). Laboratory findings are remarkable for a mild leukocytosis (WBC count, 12,000 cells/μL).

What organisms are responsible for lymphogranuloma venereum (LGV)? What is its clinical course? What subjective and objective manifestations in S.F. are consistent with LGV?

LGV or Nicolas–Favre disease has historically been considered a rare disease in the United States and other developed nations; however, outbreaks have been recently reported in the Netherlands and Great Britain as well as in the United States in New York, Texas,

and San Francisco.[65],[66] Since 2003, the number of cases of LGV, especially proctocolitis, in MSM in developed countries has been increasing.[67],[68] The cause of LGV is usually *C. trachomatis* serovars L1, L2, or L3, which are different from those serovars responsible for chlamydia urethritis.[69] Three stages of LGV infection are recognized in MSW.[70]

Stage I is characterized by a small genital papule or vesicle that appears between 3 and 30 days after exposure. The patient usually is asymptomatic; the ulcer heals rapidly and leaves no scar. This primary lesion is consistent with that reported by S.F. Many patients with LGV recall no primary lesion. Stage II is characterized by acute, painful lymphadenitis with bubo formation (the inguinal syndrome); it often is accompanied by pain and fever, as illustrated by S.F. Without treatment, the buboes may rupture, forming numerous sinus tracts that drain chronically. Adenopathy above and below the inguinal ligament results in the "groove sign." Healing occurs slowly, and most patients suffer no serious sequelae. Patients in this stage also may present with an anogenitorectal syndrome, which is accompanied by proctocolitis and hyperplasia of intestinal and perirectal lymphatic tissue. Stage III is characterized by perirectal abscesses, rectovaginal fistulae (in females), rectal strictures, and genital elephantiasis.[70] Appropriate treatment of stage II LGV usually prevents these late complications.

An acute anorectal syndrome of LGV occurs in MSM who acquire the infection through rectal receptive intercourse. In these cases, a primary anal ulcer may be noted with associated inguinal adenopathy (anal lymphatics drain to inguinal nodes). Subsequently, acute hemorrhagic proctocolitis occurs with tenesmus, rectal pain, constipation, and a copurulent, bloody rectal discharge. Rectal biopsy findings may show granulomatous colitis, mimicking Crohn disease. Perirectal pelvic adenopathy also occurs.

TREATMENT

Case 72-6, Question 2: How should S.F. be treated?

Current CDC recommendations for LGV include doxycycline 100 mg PO twice daily or, as an alternative, erythromycin base 500 mg PO four times a day for 21 days.[2] Surgical intervention may be needed for later forms of the disease. Azithromycin 1 g weekly for 3 weeks may be effective as well as fluoroquinolones, but clinical data on its use are lacking.[2]

SYPHILIS

Epidemiology

Syphilis is caused by the spirochete *Treponema pallidum.* The rates of primary and secondary syphilis in the United States increased in the late 1980s secondary to crack cocaine use (and associated unsafe sex practices), but from 1990 to 2000, rates have decreased to those reported in 1941 when reporting began, representing an 89.7% decrease since 1990.[5,71,72] However, the number of cases of primary and secondary syphilis have steadily risen since 2000, reaching a high of 35,063 cases in 2018 (**Fig. 72-4**). MSM continue to account for the majority of primary and secondary syphilis cases in 2018. Another concern is that syphilis facilitates the transmission of HIV, thus the high proportion of syphilis reported in HIV-positive MSM.[5,73] Since 2008, rates of congenital syphilis did not increase until 2013 and have continued to rise since then to a total of 1306 cases in 2018.[6] In 2018, the total case count of reported syphilis for all stages combined was the highest recorded since 1991.

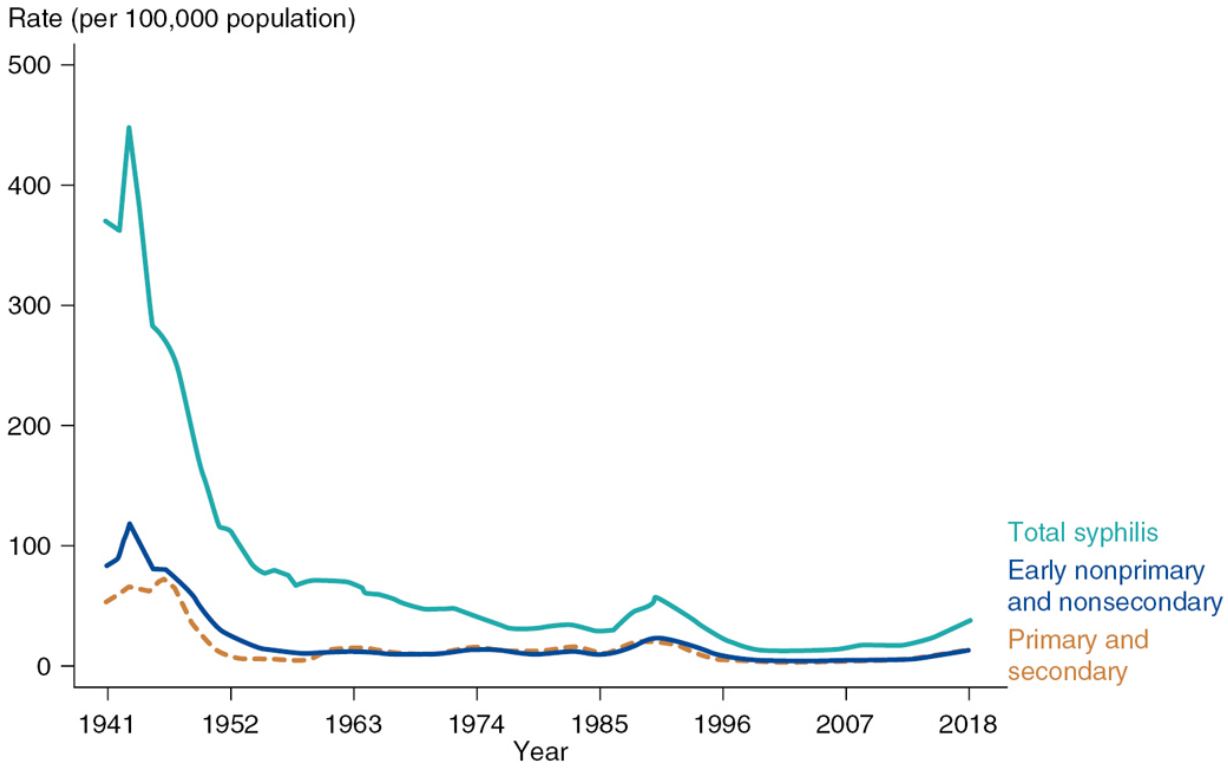

Figure 72-4 In 2018, a total of 35,063 cases of primary and secondary syphilis were reported in the United States, yielding a rate of 10.8 cases per 100,000 population. This rate represents a 14.9% increase compared with that in 2017 (9.4 cases per 100,000 population), and a 71.4% increase compared with that in 2014 (6.3 cases per 100,000 population). (Division of STD Prevention, National Center for HIV, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats18/figures/35.htm.)

The clinical manifestations of syphilis have not changed appreciably since their first description. However, early diagnosis, treatment, and greater physician/patient awareness of the disease have reduced the incidence of its severe forms. Penicillin continues to be the mainstay of therapy.

Clinical Stages

CASE 72-7

QUESTION 1: D.M., a 27-year-old MSM presents to the STD clinic with malaise, headache, and fever of 4 days' duration. He also reveals that he had a sore on his penis about 8 weeks ago, but it has since resolved. Upon examination, he is afebrile and has a widespread maculopapular skin rash that involves the soles of his feet; general lymphadenopathy also is appreciated. Medical history is unremarkable except for one episode of gonorrhea 2 years ago that was treated with procaine penicillin. Laboratory findings include a normal peripheral WBC count, negative serum for HIV antigen, and a positive rapid plasma reagin (RPR) and fluorescent treponemal antibody absorption (FTA-ABS) test results.

What is the clinical course of syphilis? Are D.M.'s symptoms consistent with this infection?

PRIMARY STAGE

The average incubation period for syphilis is 3 weeks and ranges from 10 to 90 days.[74] During this incubation period, *T. pallidum* can be demonstrated in the lymph and blood. The primary chancre develops at the site of inoculation as a painless papule that becomes ulcerated and indurated. The ulcer is nontender and filled with spirochetes. The chancre usually involves the penis in the MSW; the penis or anus in the MSM; and the vulva, perineum, or cervix in the female. Occasionally, the lip or tongue is involved. Regional lymph nodes are enlarged, firm, and nontender. Unfortunately, the typical chancre described earlier often is missed, particularly in females or MSM.[75] Without treatment, the primary chancre resolves spontaneously, usually in 2 to 6 weeks. The differential diagnosis of genital ulcers also includes chancroid and genital herpes. As with chancroid, genital herpes produces painful, superficial, nonindurated ulcers with tender inguinal adenopathy. However, unlike chancroid, lesions of genital herpes characteristically proceed through a vesicular state and often are associated with urethritis, cervicitis, and constitutional symptoms, such as fever and chills. Syphilis can be differentiated from herpes by a nonpainful versus painful lesion, a papular versus vesicular appearance, and single versus multiple lesions. Chancroid is more difficult to differentiate from syphilis, although chancroid tends to have a more tender lesion, jagged border, and striking inguinal lymphadenopathy.[74]

SECONDARY STAGE

Approximately 6 weeks after a chancre first appears, the untreated patient manifests signs and symptoms of the secondary stage of syphilis. This stage is currently evidenced by D.M. Skin lesions of secondary syphilis may erupt in a variety of patterns and are usually widespread in distribution. A macular lesion often is the earliest manifestation in this stage. The lesion is round or oval, occurs primarily on the trunk, and is rose or pink in color. As lesions mature, they become papular or nodular with scaling (the so-called papulosquamous rash). The differential diagnosis of diffuse papulosquamous rashes includes psoriasis, pityriasis rosea, and lichen planus. In syphilis, the palms and soles are characteristically involved, and oral lesions (mucous patches) may occur. Generalized lymphadenopathy usually is present, and patchy alopecia may be seen. The most infectious lesion of secondary syphilis is condyloma latum. Condylomata lata are characteristically wet, indurated lesions occurring primarily in the perineum or around the anus as a result of direct spread from the primary lesion. Laboratory study findings sometimes reveal anemia, leukocytosis, or an increased erythrocyte sedimentation rate. Other manifestations of secondary syphilis include mild hepatitis, aseptic meningitis, uveitis, neuropathies, and glomerulonephritis.[76]

LATENT STAGE

By definition, untreated, asymptomatic persons with serologic evidence for syphilis have latent syphilis. The latent stage is divided into two phases: the early latent (<1 year's duration) and late latent (>1 year's duration). In the Oslo study of patients with untreated syphilis, 25% experienced secondary relapses, usually within the first year.[77] Patients who relapse to the secondary stage are infectious; those in the late latent stage are not infectious and are immune to reinfection with *T. pallidum.*

TERTIARY STAGE

Serious morbidity and mortality are caused by pathologic progresses involving the skin, bones, central nervous system, and cardiovascular system. Infectious granulomas (gummas), the characteristic lesions of tertiary syphilis, are observed infrequently. Most gummas respond quickly to specific therapy, although if critical organs are involved (heart, brain, liver), they can be fatal.[78] The most common manifestations of syphilitic cardiovascular disease are aortic insufficiency and aortitis, with aneurysm of the ascending aorta.

Neurosyphilis may be classified as asymptomatic early or late, meningeal, parenchymatous, or gummatous. Although neurosyphilis has been a rare complication for >40 years because of the widespread use of penicillin, syphilitic meningitis, an early form of neurosyphilis, may be more common in patients who are HIV positive.[74],[79] Late neurosyphilis may be asymptomatic or accompanied by a variety of manifestations; the most common syndromes are meningovascular syphilis, general paresis, tabes dorsalis (locomotor ataxia), and optic atrophy. In patients with asymptomatic neurosyphilis, examination of the cerebrospinal fluid (CSF) typically reveals mononuclear pleocytosis, an elevated protein concentration, and a positive VDRL reaction.

Patients with asymptomatic neurosyphilis are at increased risk for experiencing neurologic disease. Meningovascular syphilis, accounting for almost 38% of all cases of neurosyphilis, typically begins abruptly with hemiparesis or hemiplegia, aphasia, or seizures.[80] General paresis is characterized by extensive parenchymal damage and includes abnormalities associated with the mnemonic PARESIS (personality, affect, reflexes [hyperactive], eye [Argyll Robertson pupil], sensorium [hallucination, delusions, illusions], intellect [decreased recent memory, calculations, judgment], and speech). Tabes dorsalis occurs after demyelinization of the spinal cord. Symptoms observed include an ataxic, wide-based gait and foot slap; paresthesias; bladder irregularities; impotence; areflexia; and loss of position, deep pain, and temperature sensation. The Argyll Robertson pupil, seen in both

paresis and tabes dorsalis, is a small, irregular pupil that reacts to accommodation but not to light.

Laboratory Tests

Case 72-7, Question 2: Evaluate D.M.'s laboratory findings.

DARK-FIELD EXAMINATION

Exudate expressed from the chancre or from condyloma latum is examined with a dark-field microscope. The diagnosis of syphilis is made if spirochetes with characteristic corkscrew morphology and mobility are present. Three dark-field examinations on consecutive days should be performed before considering the test negative in suspected primary syphilis. This technique and other methods, such as DFA and PCR, which detect *T. pallidum* directly from exudate or tissue, are definitive diagnostic methods for syphilis. Dark-field examination is the most specific and sensitive method but only with an experienced microscopist.[81,82] Because of the special methods and equipment and experience needed for this direct method of diagnosis, a presumptive diagnosis of syphilis requires use of two serologic tests.[2]

SEROLOGIC TESTS

Two types of tests are used for the diagnosis of syphilis: nontreponemal tests, which measure serum concentrations of reagin (antibody to cardiolipin-cholesterol-lecithin), and treponemal tests, which detect the presence of antibodies specific for *T. pallidum.* When the history or examination suggests primary syphilis, a nontreponemal test and a treponemal test should be performed in a clinic (see discussion on nontreponemal tests, next). The use of one test can lead to false positives and is insufficient for diagnosis.[2]

Serologic test results become reactive during the primary stage, but they may be negative at the time of presentation with primary syphilis. If initial serology and dark-field examination results are

negative, the serology should be repeated in 1 to 4 weeks to exclude primary syphilis. If the dark-field examination result is positive, an RPR may still be ordered to establish a baseline for follow-up after treatment. Serologic test results are uniformly positive in secondary syphilis.[74]

Nontreponemal tests

Nontreponemal tests detect reactivity to a cardiolipin-cholesterol-lecithin antigen, which is not specific for *T. pallidum* but can be quantified. They are inexpensive and useful for screening large numbers of people. The most widely used nontreponemal tests are the VDRL test and the RPR Card Test. The RPR Test is the most widely used because it is simpler to perform than is the VDRL. Although equally valid assays, results of the VDRL and RPR are not interchangeable; thus, the same test should be used throughout the posttreatment monitoring period.[2,83]

The result reported in the quantitative VDRL test is the most dilute serum concentration with a positive reaction. This test may be used to follow the decline in VDRL titer after effective therapy (see Case 72-7, Question 5). In some individuals, a serofast reaction occurs in which nontreponemal antibodies may remain at a low titer for up to their entire lives. When false-positive tests occur, the titer usually is low (eg, VDRL or RPR titer of 1:8).[84] In secondary syphilis, sensitivity of the RPR and VDRL approaches 100% owing to the high antibody concentrations.[85]

Treponemal tests

Specific treponemal tests, such as FTA-ABS, *Treponema pallidum* particle agglutination (TP-PA) assay, and various EIAs, confirm a positive nontreponemal test. The FTA-ABS test is the most commonly used treponemal test. Although treponemal tests are qualitative, they tend to be more specific than are nontreponemal tests because they test for specific treponemal antigens. Traditionally, treponemal tests are relatively difficult and expensive to perform and were not used for screening. However, with advances in

methods for testing, new devices have eased the use of treponemal tests, and these tests are now recommended as part of the diagnostics for syphillis.[2]

Treatment

Case 72-7, Question 3: How should D.M. be treated?

The CDC recommends penicillin G for the treatment of all stages of syphilis (**Table 72-4**).[2] Every effort should be made to rule out penicillin allergy before choosing alternative agents. Considering that penicillin-resistant *T. pallidum* has never been observed, treatment regimens for syphilis have changed relatively little during the years.

Table 72-4
Treatment Guidelines for Syphilis

Stage	Recommended Regimen	Alternative Regimen
Early (primary, secondary, or early latent)[a]	Benzathine penicillin G 2.4 million units single dose IM	Doxycycline 100 mg PO bid for 14 days *or* Tetracycline 500 mg PO qid for 14 days *or* Ceftriaxone 1 g IM/IV every day for 8 to 10 days *or* Azithromycin 2 g PO × 1 dose
Latent (>1 year) or latent syphilis of unknown duration	If CSF normal: benzathine penicillin G 2.4 million units /week × 3 week IM	If CSF normal: doxycycline 100 mg PO bid for 28 days *or*

		Tetracycline 500 mg PO qid for 28 days
	If CSF abnormal: treat as neurosyphilis	If CSF abnormal: treat as neurosyphilis
Neurosyphilis[b] (asymptomatic or symptomatic)	Aqueous crystalline penicillin G 18–24 million units IV every day × 10–14 days[c]	Procaine penicillin 2.4 million units IM daily plus probenecid 500 mg PO qid, both for 10–14 days
Congenital	Aqueous crystalline penicillin G 100,000–150,000 units/kg/day, administered as 50,000 units/kg/dose IV Q 12 hour during the first 7 days of life, and every 8 hours thereafter for a total of 10 days[d]	If CSF normal: benzathine penicillin G 50,000 units/kg/dose IM in a single dose
	or	
	Procaine penicillin G 50,000 units/kg/dose IM a day in a single dose for 10 days	
Syphilis in pregnancy	According to stage	According to stage

bid, twice a day; CSF, cerebrospinal fluid; IM, intramuscular; IV, intravenous; PO, orally; Q, every; qid, four times a day.

[a]Some experts recommend repeating this regimen after 7 days for HIV-infected patients.

[b]Because of the shorter duration of therapy as compared with latent syphilis, some experts recommend giving benzathine penicillin G, 2.4 million units/week for up to 3 weeks, after the completion of these neurosyphilis regimens to provide a comparable total duration of therapy.

[c]Administered as 3 to 4 million units IV every 4 hours or continuous infusion.

[d]All infants born to females treated during pregnancy with erythromycin must be treated with penicillin at birth.

Source: Adapted from Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1.

As shown in Table 72-4, recommended therapy for primary, secondary, or early latent syphilis (with negative findings in the CSF) of <1 year's duration is a single, IM 2.4 million unit dose of benzathine penicillin G. If penicillin is contraindicated, tetracycline 500 mg PO four times a day or doxycycline 100 mg PO twice a day for 14 days is the main alternative. If the patient is allergic to penicillin, is not pregnant, and cannot receive tetracycline or doxycycline, a 10- to 14-day regimen of ceftriaxone 1-g IM or IV every day or a single 2-g dose of azithromycin is an option.[2] The use of erythromycin as an alternative is no longer recommended by the CDC because of its poor efficacy. The optimal dose, duration, and efficacy of these alternative regimens are not well defined, necessitating close follow-up of patients. Recent studies, however, have shown that azithromycin 2 g PO as a one-time dose is at least equivalent to benzathine penicillin G.[86,87] Skin testing should be performed for individuals who claim an allergy to penicillin. If the patient is truly allergic, they should be desensitized.[2]

Late latent syphilis (>1 year's duration) and tertiary syphilis (gummas or cardiovascular syphilis with negative findings in the CSF) are treated with IM benzathine penicillin G 2.4 million units weekly for a total of 3 weeks.[2]

NEUROSYPHILIS

Case 72-7, Question 4: Would D.M.'s treatment differ if his CSF test had yielded a positive result for syphilis?

Neurosyphilis can present at any stage of syphilis. When conventional IM doses of benzathine penicillin G are administered, measurable levels of penicillin are not obtainable in the CSF. However, this does not mean that penicillin does not concentrate in meningeal tissue.[88] Treatment failures, as well as late clinical progression to neurosyphilis, can occur after treatment with the recommended IM regimen. After one dose, benzathine penicillin reaches peak plasma concentrations slower (13–24 hours) but with

more prolonged treponemicidal plasma concentrations (7–10 days) when compared with procaine penicillin (1–4 hours to peak; 12- to 24-hour treponemicidal plasma concentrations).[88] Reports of benzathine penicillin failures in the 1970s resulted in the CDC recommending treatment with aqueous crystalline penicillin G, 3 to 4 million units IV every 4 hours, or 18 to 24 million units per day continuous infusion, for 10 to 14 days. Alternatively, neurosyphilis can be treated with concurrent procaine penicillin (2.4 million units IM daily) and probenecid (500 mg PO four times a day) for 10 to 14 days. Some experts add benzathine penicillin G (2.4 million units IM once a week for up to 3 weeks) after the completion of aqueous penicillin G or procaine penicillin.[2] Penicillin-allergic patients should be skin tested to confirm allergy and, if confirmed, the patient should be desensitized and treated with an appropriate penicillin regimen. Some data suggest that ceftriaxone 2 g IM or IV daily for 10 to 14 days can be used as an alternative in patients whose concern for cross-sensitivity between ceftriaxone and penicillin is negligible.[2] Alternatively, the World Health Organization recommends penicillin-allergic nonpregnant patients receive either doxycycline 200 mg PO twice a day or tetracycline 500 mg PO four times a day for 30 days.[89]

FOLLOW-UP

Case 72-7, Question 5: D.M. was treated with a single IM dose of benzathine penicillin (2.4 million units). How should his response to therapy be monitored?

Physical examination and a quantitative VDRL or RPR test for primary and secondary syphilis should be repeated at least 6 and 12 months after therapy.[2] Retreatment should be considered when the RPR or VDRL titer does not decline fourfold in 6 months. Patients with HIV coinfection should receive periodic serologic testing.[74] Patients with latent syphilis should be retested 6, 12, and 24 months after treatment. Close serologic monitoring is necessary if antibiotics other than penicillin are used; CSF examination should be performed in these patients at their last follow-up visit. Patients with

neurosyphilis should be monitored serologically every 6 months; CSF examinations should be repeated at 6-month intervals until normal. If results are still abnormal at 2 years, retreatment should be considered. Return of lesions, a fourfold increase in titer, or a titer of 1:8 that does not fall at least fourfold within 12 months necessitates retreatment. Suspected treatment failures, especially with abnormal CSF, should be treated as described for neurosyphilis. However, false-positive serologic results should be ruled out.

Within 2 years, most patients with early syphilis become seronegative. However, if the disease is treated during the late stages, complete seroreversion may not occur. Patients treated with oral doxycycline or erythromycin are less likely to become seronegative.[90] Therapy is considered adequate in patients who never become seronegative as long as the titer decreases fourfold. Although the disease process may be halted in patients with tertiary syphilis, existing damage to the cardiovascular or nervous systems cannot be reversed.

PREGNANCY

CASE 72-8

Question 1: N.W., a 27-year-old female in her 19th week of gestation, has a positive VDRL and FTA-ABS.

How should N.W. be managed? How would management be altered in the face of penicillin allergy?

Although pregnancy may be associated with false-positive nontreponemal test results,[76] the presence of both a positive treponemal test result (eg, FTA-ABS) and a nontreponemal test result (eg, RPR) virtually excludes a false-positive reaction.[82] The next step is to determine whether N.W. already has been treated adequately. If she has previously received adequate treatment and follow-up and shows no evidence of persistence or recurrence of syphilis, then she requires no further therapy. Pregnancy has no known effect on the clinical course of syphilis.[91] However, her infant

should be observed carefully. If N.W. has not been treated previously for syphilis, then she should be treated with penicillin in the same doses recommended for nonpregnant females; some experts recommend a second dose 1 week later of 2.4 million units of benzathine penicillin.[2]

The goal of therapy should be to treat the mother with syphilis as soon as possible. Syphilis transmission can occur transplacentally as early as 9 to 10 weeks' gestation via direct contact with lesions in the birth canal.[91],[92] If the mother is left untreated, 70% to 100% of fetuses born to mothers with primary or 40% with secondary syphilis may be aborted, stillborn, or born with congenital syphilis (see Case 72-8, Question 3).[93],[94]

There is no completely satisfactory alternative for the pregnant female with an accelerated allergic reaction to penicillin. Tetracycline, as well as doxycycline, should be avoided during pregnancy, especially during the second or third trimester, because of tetracycline's known effects on the fetus (tooth staining and inhibition of bone growth).[95] Erythromycin has been used to treat pregnant patients with syphilis; however, the transplacental transfer rate of erythromycin is inadequate[96] potentially explaining the increased rate of aborted or stillborn infants in erythromycin-treated patients. Erythromycin and azithromycin are not recommended as an alternative therapy for syphilis during pregnancy.[2] A female with a history of allergy to penicillin should be skin tested; if allergy is confirmed, she should be desensitized and treated with penicillin.[2] It is possible that the newer cephalosporins may ultimately prove to be acceptable alternatives to penicillin G in the pregnant female with syphilis who is allergic to penicillin, but there is insufficient evidence for the CDC to recommend their use. Adequate treatment with penicillin can prevent up to 98% of fetal infections.[97],[98] Serologic titers, at a minimum, should be followed up at 28 to 32 weeks' gestation and at delivery. Monthly serologic titers may be considered in females at high risk for reinfection or those in geographical areas of high syphilis rates; thereafter, she should be followed up as any other patient with syphilis.[2]

JARISCH–HERXHEIMER REACTION

Case 72-8, Question 2: N.W. was treated with an IM injection of 2.4 million units of benzathine penicillin G. Six hours later, N.W. experienced diffuse myalgias, chills, headache, and an exacerbation of her rash. She was tachypneic, but normotensive. What is this reaction? How should N.W. be managed?

N.W. has developed the Jarisch–Herxheimer reaction (JHR), a usually benign, self-limited complication of antitreponemal antibiotic therapy that develops within hours of treatment of early syphilis.[2] The cause of JHR is not well understood but is probably related to release of cytokines.[99] Clinical manifestations include fever, chills, myalgias, headache, tachycardia, and hypotension. The pathogenesis of the syndrome is uncertain, but the reaction should not be interpreted as an allergic reaction to penicillin. It typically begins within the first 24 hours of antibiotic administration and normally subsides spontaneously, generally subsiding even while antibiotics are continued.[2,100] Notably, JHR can occur after administration of many antimicrobials and is not exclusive to penicillins, nor is it exclusive to syphilis treatment, occurring in other spirochetal diseases such as Lyme disease and relapsing fever.[101] Usually self-limiting in nonpregnant patients, the primary risk of this reaction in pregnant females is miscarriage, premature labor, or fetal distress.[2,102] Pregnant females should seek medical attention if contractions or a change in fetal movements are noted. Close monitoring of JHR should be observed in patients with ophthalmic or neurologic syphilis. For these patients, prednisolone 10 to 20 mg three times a day for 3 days given 24 hours before syphilis treatment may prevent fever, but it will not control local inflammation.[88] Tumor necrosis factor-α has been demonstrated to have some success in the prevention of JHR in spirochete disease.[103] Although there is no proven effective preventive therapy, some experts still recommend antipyretics, hydration, and patient education; antibiotic therapy should not be discontinued.

NEONATAL SYPHILIS

CASE 72-8, QUESTION 3: How should N.W.'s baby be treated if a diagnosis of congenital syphilis is confirmed?

Infants born to mothers who have been treated for syphilis during pregnancy should be carefully examined at birth with a quantitative nontreponemal serologic test. If tests are reactive, the infant should be followed up and have serologic testing done every 2 to 3 months until nontreponemal tests are nonreactive.[2] Newborn serology is difficult to interpret because of transplacental transfer of nontreponemal and treponemal IgG to the infant. Treatment decisions are largely based on evidence of syphilis in the mother, adequacy of maternal treatment, comparison of maternal and neonatal nontreponemal serology, and/or presence of clinical or laboratory evidence of syphilis in the neonate. In addition, infants should be treated at birth, even if they are asymptomatic, when maternal treatment is unknown or inadequate, or when infant follow-up cannot be guaranteed. In most cases, a CSF examination should be performed before treatment is begun to rule out neurosyphilis.

CHANCROID

Chancroid or soft chancre is a painful genital ulcer disease that often is associated with tender inguinal adenopathy. It is caused by *H. ducreyi,* a gram-negative bacillus. Chancroid is endemic in developing countries, but its incidence in the United States has steadily declined. Since 2011, cases of chancroid in the United States have been <100; and in 2018, only three cases were reported.[6] Chancroid and other genital ulcers have also been implicated in the acquisition and transmission of HIV.

Signs and Symptoms

CASE 72-9

QUESTION 1: T.G., a 31-year-old uncircumcised sexually active male, presents to the STD clinic with tender lesions on the penis and inguinal regions. He noticed the penile lesions on the external surface of the prepuce (foreskin) 2 days before his visit. The lesions were sharply demarcated but were not indurated; the base of the penile ulcer was covered by a yellow-gray purulent exudate. Right inguinal adenitis was present and extremely painful on palpation. A dark-field examination result of the purulent exudate was negative. Gram stain revealed a mixture of gram-positive and gram-negative flora. T.G. claims to have an allergy to penicillin, but no other drug allergies are reported.

What is the natural course of chancroid? Does T.G. have signs or symptoms consistent with chancroid? What diagnostic procedures are necessary?

Uncircumcised males may have an increased risk of chancroid infection and may not respond to therapy as well as circumcised males do. In fact, evidence suggests circumcision is protective against nearly all STDs, including HIV, as well as protecting females against *T. vaginalis* and BV.[2] A painful genital ulcer appears 3 to 10 days after exposure and begins as a tender, red papule that becomes pustular and ulcerates within 2 days. Chancroid can be suspected if all of the following criteria are met: (a) one or more painful genital ulcers present, (b) regional lymphadenopathy, (c) no evidence of T. *pallidum* by dark-field examination, and (d) a negative result in the HSV PCR test or HSV culture. As illustrated by T.G., the ulcer may be covered by a grayish or yellow exudate. A Gram stain can be misleading because of the polymicrobic nature of the ulcer and culture and because isolation of *H. ducreyi* is difficult, requiring specialized specimen collection and growth media.[2]

Treatment

CASE 72-9, QUESTION 2: How should T.G.'s chancroid be treated?

Most strains of *H. ducreyi* produce a TEM-type β-lactamase, and many strains are resistant to the antimicrobials that traditionally were used to treat chancroid, such as sulfonamides and tetracycline.[104,105]

Currently recommended CDC treatment regimens include azithromycin 1 g PO for 1 dose, ceftriaxone 250 mg IM once, ciprofloxacin 500 mg PO twice a day for 3 days, or erythromycin base 500 mg PO three times a day for 7 days. Ciprofloxacin is contraindicated in pregnant and lactating females. Because T.G. has a history of penicillin hypersensitivity, azithromycin as a single oral dose is a preferred treatment regimen. Treatment may not be as effective for patients who are coinfected with HIV or who are uncircumcised and, therefore, HIV testing should occur at the time of chancroid diagnosis. If the result is negative, the test should be repeated 3 months after the diagnosis. Follow-up should occur 3 to 7 days after treatment is initiated. Depending on the size of the ulcer, the time required until complete recovery will vary; larger ulcers may require longer than 2 weeks. Because T.G. is also sexually active, his sexual partner should be evaluated and treated if they had contact during the 10 days before the onset of symptoms.[2]

VAGINITIS

Approximately 10 million physician office visits are made annually in the United States for females seeking evaluation and treatment of vaginitis.[106] The term *vaginitis* refers to such nonspecific vaginal symptoms as itching, burning, irritation, and abnormal discharge that may be caused by infection or other medical conditions. The most common vaginal infections are BV (22%–50% of cases), vulvovaginal candidiasis (VVC; 17%–39% of cases), and trichomoniasis (4%–35% of cases). However, up to 30% of cases of vaginitis remain undiagnosed.[107]

Bacterial Vaginosis

BV was not described clearly as a syndrome (initially called *H. vaginalis* vaginitis) until the 1950s. BV is the most common genital tract disorder among reproductive age females.[108] Although the

exact prevalence of BV varies based on race/ethnicity, the National Health and Nutrition Examination Survey (NHANES) data estimate it to be 29.2%. Many females harbor *G. vaginalis*, the most commonly implicated organism, yet up to 84% are asymptomatic.[108] During an episode of BV, normally predominant lactobacilli are replaced with an overgrowth of *G. vaginalis*, *Atopobium vaginae, and other* anaerobic species such as *Mobiluncus*, *Prevotella*, *Bacteroides*, *Fusobacterium*, *Ureaplasma*, and *Mycoplasma.* This shift in vaginal flora results in a malodorous discharge, and the paucity of lactic acid and peroxide-producing lactobacilli leaves the mucosa vulnerable to other infections.

BV may be more accurately described as vaginal ecosystem imbalance, in which multiple organisms are implicated. The evidence for definitive risk factors in BV is inconclusive. Multiple sexual partners, a new sexual partner, douching, smoking, lack of condom use, and antibiotic use have been associated with BV. Any female may develop BV, although nonsexually active females are rarely affected.[2] In addition, studies among females who have sex primarily with females show evidence for sexual transmission.[109] The routine treatment of male sexual partners is not recommended because a female's response to therapy, as well as her likelihood of relapse or recurrence is not impacted by treatment of her sexual partner(s).[2]

SIGNS, SYMPTOMS, AND DIAGNOSIS

CASE 72-10

Question 1: H.H. is a 24-year-old, sexually active female with a 1-week history of moderate vaginal discharge that has a "fishy" odor, most notable after coitus. She has no vaginal pruritus or burning. On examination, the discharge appears thin, white, homogeneous, and notably malodorous. A wet mount of the vaginal secretion revealed rare leukocytes and numerous "clue cells." The vaginal pH was 5.0, and a characteristic fishy odor was noted when the discharge was mixed with 10% potassium hydroxide (KOH).

Does H.H. have signs and symptoms consistent with BV? Are additional diagnostic tests required?

H.H.'s signs and symptoms are typical of BV. The gold standard diagnostic test is a Gram stain of the vaginal discharge showing overgrowth of *G. vaginalis* and other anaerobes with low numbers of lactobacilli (Nugent score). Clinical diagnosis is confirmed by noting the presence of at least three of four Amsel criteria: (a) 10% KOH solution mixed with the vaginal discharge yields a fishy odor from increased biogenic diamines (positive "whiff" test); (b) saline mount of the specimen reveals >20% "clue cells" (vaginal epithelial cells with adherent coccobacilli); (c) vaginal pH measures >4.5; and (d) vaginal discharge is characteristically thin, milky-gray, and homogeneous.[110] Vaginal cultures are not helpful because up to 60% of the results from healthy, asymptomatic females will be positive for *G. vaginalis*. DNA probes for *G. vaginalis* and immunochromatographic testing for vaginal sialidase are available but add to the cost of diagnosis. If there are many white cells on wet mount, other infections (eg, *T. vaginalis*) should be suspected, because BV, by definition, is noninflammatory. Self-diagnosis is correct only 3% to 4% of the time because most females attribute symptoms to poor hygiene.[111]

TREATMENT

CASE 72-10, QUESTION 2: How should H.H. be treated?

Females with symptomatic disease require treatment. CDC-recommended regimens include oral metronidazole 500 mg twice a day for 7 days, metronidazole gel 0.75% intravaginally daily for 5 days, or clindamycin cream 2% intravaginally at bedtime for 7 days.[2] The FDA has approved metronidazole extended release 750 mg PO once daily for 7 days and a single dose of clindamycin intravaginal cream for the treatment of BV; however, limited data have been published comparing these regimens to established therapies. Alternatively, the CDC recommends either tinidazole 2 g PO every day for 2 days, tinidazole 1g PO every day for 5 days, clindamycin 300 mg PO two times a day for 7 days, or clindamycin ovules 100

mg intravaginally once at bedtime for 3 days.[2] Patients should be instructed to avoid consuming alcohol during treatment with metronidazole and for 72 hours afterward to avoid disulfiram-like reactions. In addition, clindamycin cream is oil based and may weaken latex condoms or diaphragms. Alternative products include oral probiotics, which have been evaluated in nonpregnant females and have shown to improve cure rates and reduce the reoccurrence of BV, although more studies are needed to establish their role in treatment.[111]

BV has been associated with preterm labor and premature delivery, and treatment is recommended for all symptomatic pregnant females. The CDC recommends metronidazole 250 mg PO three times daily for 7 days or 500 mg PO twice a day for 7 days, or clindamycin 300 mg PO twice daily for 7 days. Teratogenic studies suggest that metronidazole is not harmful to the fetus, and more recent data suggest that the use of intravaginal clindamycin cream is also safe to use for pregnant females.[2]

Vulvovaginal Candidiasis

Candida albicans is the causative organism of VVC in 80% to 92% of cases, with *C. glabrata* and *C. tropicalis* accounting for most of the remaining cases.[2] The latter have been identified increasingly as the causative agents of VVC during the past two decades. Approximately 75% of females will experience at least one episode of VVC during their reproductive years, and 40% to 45% will have two or more episodes within their lifetime.[107] Less than 5% of females who have VVC have recurrent episodes (defined as four or more episodes of VVC in 1 year). VVC is not usually described as an STD because celibate females may also experience it; however, the incidence of VVC increases when females become sexually active.[112] Because of this, VVC is often diagnosed during evaluation for a suspected STD when females present with vaginal symptoms.

ASSESSING SELF-TREATMENT

CASE 72-11

QUESTION 1: L.L., a 23-year-old female, purchases a nonprescription antifungal agent to relieve vaginal symptoms that she believes are caused by a vaginal yeast infection. L.L. asks the pharmacist for assistance in the selection of an antifungal agent.

What information should be obtained from L.L. before a medication is recommended?

The pharmacist should ask L.L. if this is her first episode of vaginitis or whether she has experienced similar symptoms previously that have been diagnosed and treated as a vaginal yeast infection by a qualified medical practitioner. The nonprescription antifungal agents are indicated for the treatment of VVC in females who previously were diagnosed and treated by a clinician. Additional questions that should be asked by the pharmacist include current symptoms, whether she is pregnant, other current medical conditions or medications, and medication allergies. Patients should be referred to a medical practitioner if any of the following are present: a first episode of VVC; four or more episodes of VVC within the past 12 months; last episode was <2 months ago; pregnancy; age younger than 12; or the presence of fever, lower abdominal or back pain, severe symptoms, or a malodorous vaginal discharge.[113]

SIGNS AND SYMPTOMS

CASE 72-11, QUESTION 2: L.L. has experienced two episodes of vaginal yeast infections, with the most recent case occurring ~1 year ago. On both occasions, she was diagnosed by a physician as having VVC and responded to antifungal therapy. L.L. currently describes vaginal and vulvar itching, vaginal soreness, and vulvar burning accompanied by a thick, white vaginal discharge that has the consistency of cottage cheese. She has been unable to have sexual intercourse because of pain. These symptoms are similar to those she experienced with her previous vaginal yeast infections. L.L. has no underlying major health problems. Her current medications include oral tetracycline for acne and Ortho Tri-Cyclen® for birth control. She has regular menstrual cycles and her last menstrual period ended 4 days ago. What clinical manifestations does L.L. exhibit that are consistent with VVC? What are other common manifestations?

L.L. exhibits signs and symptoms associated with VVC: vulvar and vaginal pruritus, vaginal soreness, vulvar burning, dyspareunia, and a thick, white nonodorous vaginal discharge that appears to be curdlike. Vulvar erythema may also be present.

DIFFERENTIAL DIAGNOSIS

Case 72-11, Question 3: How can VVC be differentiated from other vaginal infections?

VVC should be differentiated from other vaginal infections because a nonprescription antifungal agent could delay the appropriate treatment of other vaginal infections. The physical appearance of the vaginal discharge may be useful in predicting VVC if it is a viscous, nonodorous, white, curdlike discharge and the patient has a normal vaginal pH (pH <4.5). The quantity of the discharge may be scanty to profuse. Some females with VVC exhibit only vulvovaginal erythema with minimal discharge or an increased amount of normal vaginal secretion. **Table 72-5** characterizes the vaginal discharges associated with VVC, BV, and trichomoniasis. The vaginal discharge from a female with signs and symptoms of VVC should be examined microscopically for the presence of *Candida* using a wet-mount preparation with 10% KOH. The use of KOH improves the visualization of yeast or pseudohyphae that are seen in ~70% of females diagnosed with VVC. If the wet-mount finding is negative, the patient's vaginal discharge should be cultured for *Candida* in an appropriate growth medium. Isolation of *Candida* without signs and symptoms should not result in treatment, because *Candida* is part of normal vaginal flora in ~10% to 20% of females. It is the proliferation of *C. albicans* or other yeasts that lead to vulvovaginitis symptoms. Nonprescription home screening tests that measure pH levels of the vaginal discharge (eg, Vagisil Screening Kit® and Fem-V®) are also available; they are highly sensitive to pH changes but lack diagnostic specificity.

Table 72-5
Characteristics of Vaginal Discharge

Characteristics	Normal	Candidiasis	Trichomoniasis	Bacterial Vaginosis
Color	White or clear	White	Yellow-green	White to gray
Odor	Nonodorous	Nonodorous	Malodorous	Fishy smell
Consistency	Floccular	Floccular	Homogeneous	Homogeneous
Viscosity	High	High	Low	Low
pH	<4.5	4–4.5	5–6.0	>4.5
Other characteristics		Thick, curdlike	Frothy	Thin

Physiologic vaginal discharge and symptomatic normal pH vulvovaginitis

Case 72-11, Question 4: Do females such as L.L., who have an increased vaginal discharge and symptoms consistent with VVC, necessarily have a vaginal infection?

Although the possibility of vaginal infection must be addressed when a female presents with an increased vaginal discharge with or without symptoms, other conditions are associated with an increased discharge. First, a physiologic vaginal discharge must be distinguished from a pathologic discharge. Physiologic discharges (Table 72-5) characteristically are nonodorous, white or clear, highly viscous or floccular, and acidic (pH ~4.5). Physiologic discharge may also become more profuse at midcycle secondary to increased cervical mucus or vaginal epithelial cell exfoliation. Other non-infectious conditions resulting in excessive vaginal discharge include retention of foreign bodies (eg, tampons) and allergic reactions or contact dermatitis secondary to the use of vaginal spermicidal agents, soaps, deodorants, douches, vaginal lubricants, and condoms. Episodes of vulvovaginitis-like symptoms can be associated with frequent use of hot tubs, Jacuzzi baths, or swimming

pools that contain chemically treated water with high levels of chlorine.[114]

RISK FACTORS FOR VULVOVAGINAL CANDIDIASIS

CASE 72-11, QUESTION 5: What specific groups of females are most susceptible to VVC? Does L.L. fit into any group at high risk for VVC?

C. albicans colonization and symptomatic VVC increase during pregnancy and with use of high-estrogen–containing oral contraceptives. Estrogens increase binding affinity of vaginal epithelial cells to *C. albicans*.[115] Females with high glycogen concentrations (eg, uncontrolled or poorly controlled diabetes mellitus), females with depressed cell-mediated immunity secondary to disease (eg, cancer, HIV infection), and females receiving broad-spectrum antibiotics or immunosuppressive drugs (eg, cytotoxic agents, corticosteroids) are also at risk for VVC.[113] Individual cases of VVC, although not related to intercourse, may be related to orogenital sex.

L.L. is taking tetracycline, which may increase her risk for VVC. Antibacterials increase the risk for *C. albicans* overgrowth by suppressing the normal vaginal flora (eg, lactobacilli), which are normally protective. L.L. is also taking a low-estrogen–containing oral contraceptive; however, low-dose oral contraceptives have not been consistently associated with an increased risk of VVC. The use of diaphragms, vaginal sponges, and IUDs also may be risk factors for VVC.[113]

Stress-induced VVC and an increased incidence of VVC before menstruation have been described.[115] The cause of both is currently unknown. Although various dietary factors have been postulated as a cause of vaginal yeast overgrowth, the role of diet in the development of VVC remains inconclusive.[115]

TREATMENT OF VULVOVAGINAL CANDIDIASIS

Vaginally administered azoles

Case 72-11, Question 6: What vaginally administered therapy is effective for L.L.'s VVC?

L.L. is an appropriate candidate for nonprescription therapy (Table 72-6) because she had previous vaginal yeast infections with symptoms similar to those she currently is experiencing and her VVC is uncomplicated (defined as sporadic disease with mild-to-moderate symptoms in an immunocompetent host). When a patient's VVC appears complicated (defined as a recurrent infection, severe symptoms, non-*C. albicans* infection, or the presence of uncontrolled diabetes, immunosuppression, and/or pregnancy), she should be referred to her medical practitioner.[2] L.L. should respond well to short-term topical azole therapy. In addition, L.L. should ask her physician whether continuation of antibiotics is truly needed. If L.L. had been evaluated by her physician, a prescription for single-dose oral fluconazole or 3-day intravaginal therapy might have been an option.

The available azole antifungals are equally effective in treating VVC with cure rates between 80% and 90% when a full course of therapy is completed.[2] All the azole antifungal products listed in **Table 72-6** are superior to nystatin, which is no longer recommended by the CDC.[2] The medication used to treat L.L.'s VVC should be selected based on response or failure to previous therapy, convenience, ease of use, length of therapy, dosage form, and cost. L.L. should select a non–oil-based product if a latex condom or a diaphragm is used as a form of contraception (Table 72-6).

Table 72-6
Recommended Regimens for the Treatment of Candida Vulvovaginitis

Drug	Availability	Trade Names	Dosing Regimens
Nonprescription Products			
Butoconazole	2% vaginal cream[a]	Femstat 3®	Nonpregnant females: Administer 1 applicatorful intravaginally qhs for 3 consecutive days.
			Pregnant females during second and third trimesters: Administer 1 applicatorful intravaginally qhs for 7 consecutive days.
Clotrimazole	1% vaginal cream[a]	Gyne-Lotrimin 7®; Mycelex-7®; Clotrimazole 7®; various generics	Administer 1 applicatorful intravaginally qhs for 7–14 consecutive days.
	2% vaginal cream[a]	Gyne-Lotrimin 3®; various generics	Administer 1 applicatorful intravaginally qhs for 3 consecutive days.
Miconazole	2% cream[a]	Monistat 7®; Femizol-M®; various generics	Administer 1 applicatorful intravaginally qhs for 7 consecutive days.
	4% cream[a]	Monistat 3®; various generics	Administer 1 applicatorful intravaginally qhs for 3 consecutive days.
	100-mg vaginal suppositories[a]	Monistat 7®	Insert 1 suppository intravaginally qhs for 7 consecutive days.
	200-mg vaginal suppositories[a]	Monistat 3®	Insert 1 suppository intravaginally qhs for 3 consecutive days.
	1200-mg vaginal suppositories[a]	Monistat 1 Daytime Ovule	Insert 1 suppository intravaginally qhs for 1 dose only.
Tioconazole	6.5% vaginal ointment	Vagistat-1®	Administer 1 applicatorful intravaginally at qhs for 1 dose only.
Prescription Products			
Butoconazole	2% vaginal cream[a]	Gynazole 1®	Nonpregnant females: Administer 1 applicatorful qhs for 1 dose only.
Fluconazole	150-mg oral tablet	Diflucan®	Take 1 tablet PO for 1 dose only.
Terconazole	0.4% vaginal cream[a]	Terazol 7®	Administer 1 applicatorful intravaginally qhs for 7 consecutive days.
	0.8% vaginal cream[a]	Terazol 3®	Administer 1 applicatorful intravaginally qhs for 3 consecutive days.
	80-mg vaginal suppositories[a]	Terazol 3®	Insert 1 suppository intravaginally qhs for 3 consecutive days.

PO, orally; qhs, at bedtime.

[a]The Centers for Disease Control and Prevention (CDC) states that the use of vaginally administered oil-based preparations may weaken latex products such as condoms and diaphragms.

Source: Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4): 1–187. doi:10.15585/mmwr.rr7004a1.

Other treatments for acute vulvovaginal candidiasis

Oral lactobacillus and lactobacillus-containing yogurt are advocated for the treatment of VVC; however, evidence in support of this treatment is inconclusive.[116] Boric acid 600 mg capsules inserted in the vagina at bedtime for 14 days are effective for the treatment of recurrent VVC with eradication rates of 70%, but vaginal burning and irritation are common side effects and it is poisonous if inadvertently

ingested.[2],[116] Gentian violet preparations also have limited use in the treatment of candidiasis because they stain clothing and bed linens and cause local irritation and edema.

Oral azoles

Case 72-11, Question 7: How effective are orally administered azoles in the treatment of an acute VVC infection such as the one L.L. is experiencing?

Fluconazole is the only oral antifungal agent currently recommended by the CDC for the treatment of acute VVC. A single 150-mg oral dose of fluconazole is as effective as a 3- to 6-day regimen of intravaginal clotrimazole.[117] Patient preference should be a factor in treatment choice, and many females may prefer the convenience of an oral over intravaginal therapy; however, systemic therapy for mild-to-moderate VVC is of some concern because of the potential for systemic adverse effects.[118]

Adverse Effects Associated With Azoles

Case 72-11, Question 8: What adverse effects might L.L. experience from intravaginally or orally administered azoles?

When used intravaginally, azoles are associated with dose-dependent adverse reactions similar to symptoms females report from VVC. Thus, it can be difficult to differentiate disease symptoms from adverse drug reactions. If the vaginal symptoms worsen after therapy is started, the patient should contact her health care provider. In addition, if symptoms have not improved within 3 days of initiation of therapy or continue past 7 days, the patient should contact her provider to rule out more severe disease or treatment of the wrong disease.[113] Topical azole therapy is generally well tolerated but has been associated with a variety of side effects including headaches, allergic contact dermatitis, vulvovaginal pruritus and irritation, dyspareunia, and general burning, soreness,

and genital pain. Oral fluconazole is also well tolerated but has been associated with headaches, nausea, abdominal pain, diarrhea, dyspepsia, dizziness, taste perversion, angioedema, Stevens–Johnson syndrome, anaphylaxis, and cardiac arrhythmia. It has also been associated with drug–drug interactions with several commonly prescribed drugs (eg, sulfonylureas, statins, proton-pump inhibitors, benzodiazepines, selective serotonin reuptake inhibitors, tricyclic antidepressants). Intravaginal miconazole has been reported to interact with warfarin, increasing the risk of bleeding and bruising.[119]

PATIENT COUNSELING

Case 72-11, Question 9: How should L.L. be counseled about the use of a nonprescription vaginal antifungal product?

The details of intravaginal administration should be reviewed with L.L., including instructions on how to clean the applicator. To minimize leakage and annoyance, L.L. should apply the product at bedtime, which increases vaginal retention. She should be advised that the nonprescription vaginal antifungal creams and suppositories are oil based and thus may weaken condoms or diaphragms, thereby reducing their effectiveness.

L.L. should be informed about the importance of completing a full course of therapy even if her symptoms subside beforehand and to continue her antifungal treatment through her menstrual period should it occur. In addition, L.L. should be instructed to see her medical provider if her symptoms persist, if she experiences symptoms that may signal a more serious problem (eg, abdominal pain, fever, a foul-smelling or bloody vaginal discharge), and/or if another yeast infection occurs within 2 months.

L.L. may be advised to avoid wearing tight-fitting, unventilated underwear (eg, nylon panties or pantyhose) and tight-fitting jeans because a warm, moist environment can facilitate fungal growth. However, one study addressing risk factors for VVC found no relation between type of underwear and the incidence of VVC.[120] In

fact, many risk factors for VVC are not consistently associated with this infection.[113] L.L. also could be alerted to the possible relation between candidiasis and swimming in a heavily chlorinated pool or frequent use of a Jacuzzi or hot tub.

Complicated Vulvovaginal Candidiasis

Case 72-11, Question 10: How would the management of L.L.'s VVC differ if she had poorly controlled diabetes?

VVC in a female with uncontrolled diabetes is usually considered to be complicated VVC. A diagnosis of complicated VVC is also warranted when the VVC is severe, recurrent, caused by non-C. *albicans* species, or when VVC occurs in an immunosuppressed, debilitated, or pregnant female. The treatment of complicated VVC varies depending on the underlying reason. Severe VVC (eg, extensive vulvar erythema, edema, excoriation, and fissures) may be treated with either a 7- to 14-day course of topical azoles or two oral doses of fluconazole 150 mg given 72 hours apart. Infection with non-*C. albicans* species should be treated with a 7- to 14-day course of an oral or intravaginal azole; however, the optimal treatment is unknown. Oral fluconazole has poor activity against non-*C. albicans* species and should not be used. Boric acid 600 mg capsules administered intravaginally once daily for 14 days can also be used, showing eradication rates of 70%.[2]

Recurrent Vulvovaginal Candidiasis

Case 72-11, Question 11: L.L. experiences another case of VVC 1 month later. Does she have recurrent VVC? How should she be treated?

Most females have only occasional episodes of VVC, but ~5% experience recurrent VVC infections. To determine whether L.L. has recurrent VVC, a diagnosis of *Candida* needs to be confirmed by

vaginal cultures. Then, underlying risk factors for VVC, such as HIV infection, uncontrolled diabetes mellitus, consumption of excess sugars, IUD placement, and use of antibiotics, must be ruled out.[121] Based on the timing of L.L.'s episodes and the absence of risk factors, L.L. does not meet the definition for recurrent VVC. If a patient meets the criteria for recurrent VVC, an underlying cause of the problem may not be determined. In addition, the role of sexual transmission is not currently well understood.[112] In most patients, the pathogenesis of recurrent VVC cannot be determined.

Treatment of recurrent (more than four episodes in 12 months) *C. albicans* vulvovaginitis should include a prolonged, 7- to 14-day course of topical therapy or a three-dose regimen of oral fluconazole (100, 150, or 200 mg) administered every 3 days. A 6-month maintenance regimen should be initiated after remission has been achieved (**Table 72-7**). Despite the efficacy of these regimens, discontinuation of therapy after 6 months can result in relapse in 30% to 50% of females.[2] Azole-resistant strains of *C. albicans* are rare; therefore, culture and sensitivity testing is not usually performed to help guide treatment before initiation.

Table 72-7
Maintenance Regimens for Recurrent Vulvovaginal Candidiasis

	Dose	Frequency
Topical agents[a]		
Clotrimazole	200 mg	Intermittently
Clotrimazole vaginal suppositories	500 mg	Intermittently
Oral agents		
Fluconazole tablets	100, 150, or 200 mg	Weekly for 6 months

[a]Given as examples only; the Centers for Disease Control and Prevention (CDC) does not indicate a preferred regimen.

Vulvovaginal Candidiasis During Pregnancy

Case 72-11, Question 12: What teratogenic risks are associated with the use of azole preparations?

Vaginal colonization with *Candida* and symptomatic VVC are common during pregnancy.[120] Asymptomatic colonization is not associated with increased maternal or fetal risks and need not be treated; however, symptomatic VVC should be treated.[122] Although doses of oral fluconazole used to treat VVC have not been associated with increased fetal defects, higher doses may be teratogenic. Therefore, topical antifungal agents are preferred for the treatment of VVC in pregnant females. The CDC currently recommends a 7-day course of topical antifungal therapy for VVC during pregnancy; however, a 3-day regimen with appropriate follow-up to assess efficacy has been shown to be effective in mild-to-moderate cases. Clotrimazole is also classified as a category B drug for fetal risk, and the remaining vaginally administered azoles are designated as category C.[122]

Trichomoniasis

SIGNS AND SYMPTOMS

CASE 72-12

Question 1: N.B. is a 31-year-old female with a recent history of profuse vaginal discharge and irritation. Examination confirms the presence of an increased, yellow-green vaginal discharge. A wet-mount examination of vaginal secretions revealed numerous motile flagellates.

What subjective and objective clinical data support a diagnosis of trichomoniasis?

Trichomoniasis is the most common curable (nonviral) STD in the United States; it is caused by the protozoan *T. vaginalis.*[2] The overall prevalence is estimated at 3.1%, with the highest prevalence among African Americans at 13.3%. Trichomoniasis in females is

asymptomatic or with minimal symptoms about 70% to 85% of the time. In males, *T. vaginalis* most commonly infects the urethra, although it may also cause epididymitis and prostatitis. Classic symptoms of trichomoniasis in females include a profuse, frothy, yellow-green malodorous discharge with pruritus and dysuria. On speculum exam, a "strawberry" cervix (cervical microhemorrhages) may be noted in 2% to 25% of cases.[123] In almost all cases of trichomoniasis, a vaginal pH >5 is observed.[124] Although trichomonads are easily visualized on a Papanicolaou (Pap) test, it is associated with a 48.4% error in diagnosis when used alone.[123] Direct microscopic observation of trichomoniasis using a wet mount is inexpensive and yields a high specificity, but it has a low sensitivity.[26] Other testing options include culture, rapid antigen tests, and NAATs.

Treatment

METRONIDAZOLE AND TINIDAZOLE

Case 72-12, Question 2: How should N.B.'s trichomoniasis be treated?

The only class of drugs that is effective for the treatment of trichomoniasis is nitroimidazoles. In the United States, metronidazole and tinidazole are the only available nitroimidazoles, and both are CDC-recommended first-line agents given as a single 2-g oral dose. Sexual partners should be simultaneously treated to prevent reinfection. Although females should be tested for reinfection in 3 months, there are currently no data to support retesting males posttreatment. Metronidazole cure rates are reported to be 84% to 98%, whereas tinidazole cure rates are reported to be 92% to 100%; concurrently treating sexual partners might increase these rates. Tinidazole offers other advantages such as higher serum and genitourinary levels, a longer half-life, and fewer GI adverse reactions.[2]

Approximately 4% to 10% of *T. vaginalis* isolates exhibit a low-level resistance to metronidazole therapy and 1% to tinidazole therapy; however, higher level resistance appears to be rare.[2] If metronidazole 2 g PO for one dose fails and reinfection is excluded, metronidazole 500 mg PO twice daily for 7 days can be used. However, if this regimen fails, either metronidazole or tinidazole 2 g PO as a single dose for 7 days should be used. In the case of allergy to nitroimidazole compounds, patients should be desensitized to metronidazole and subsequently treated.[2]

ADVERSE EFFECTS

Case 72-12, Question 3: N.B. was treated with metronidazole 2 g as a single dose; however, while attending a party, N.B. experienced a severe headache, followed by nausea, sweating, and dizziness. Could N.B.'s symptoms be caused by metronidazole?

Minor side effects associated with metronidazole therapy include nausea, vomiting (especially with single-dose therapy), headache, skin rashes, and alcohol intolerance. The alcohol intolerance may be attributable to a metronidazole-induced inhibition of aldehyde dehydrogenase, which results in the buildup of high serum acetaldehyde levels, although the true risk of this interaction has been debated.[125] According to the manufacturer, patients should be warned about the possibility of nausea, vomiting, flushing, and respiratory distress after alcohol consumption, although reliable evidence is lacking.[120] As a general rule, patients should avoid alcohol ingestion during treatment and for 72 hours after metronidazole or tinidazole therapy. In those patients who cannot otherwise tolerate oral metronidazole or tinidazole, a combination of intravaginal miconazole and metronidazole may be an effective alternative.[126]

PREGNANCY

CASE 72-13

QUESTION 1: S.G., a 31-year-old female, is in her first trimester of pregnancy and has a history of recurrent trichomoniasis. She now has a profuse, yellow vaginal discharge. The preliminary diagnosis of trichomoniasis is confirmed by a wet-mount examination of vaginal secretions revealing numerous trichomonads. S.G. has read much lay press on metronidazole and is concerned about the health of her fetus.

Can metronidazole be used for S.G.?

During pregnancy, trichomoniasis infection is associated with premature rupture of the membranes, preterm delivery, and low birth weight; thus, current guidelines recommend treatment in all symptomatic pregnant females in any trimester.[2] Historically, there has been concern about the administration of metronidazole during the first trimester; it is mutagenic in facultative bacteria, and long-term, high-dose metronidazole in laboratory mice is associated with the development of pulmonary and hepatic tumors. Although midline facial defects have been documented in humans, numerous recent studies have found that metronidazole is not a teratogen.[127] The use of metronidazole in asymptomatic females has not been shown to decrease rates of preterm labor despite eliminating the organism from its host.[127]

Treatment

CASE 72-13, QUESTION 2: How should S.G. be treated?

All symptomatic pregnant females should be treated with metronidazole 2 g PO as a single dose, and sexual partners should also be treated. Metronidazole is classified as pregnancy category B. Tinidazole 2 g PO as a single dose could be suggested as an alternative regimen; however, it is classified as pregnancy category C.[2]

GENITAL HERPES

The word *herpes* is of Greek origin and means "to creep."[128] HSV is a DNA-containing virus that consists of two antigenically distinct serotypes: HSV-1 and HSV-2. The primary cause of herpes labialis (cold sores), herpes keratitis, and herpetic encephalitis is HSV-1. Genital herpes and neonatal herpes primarily are the result of HSV-2 infections. Among males who were diagnosed with genital herpes between 2011 and 2016, 25.2% were HSV-2 positive/HSV-1 negative, which is similar to previously reported rates from 1999 to 2010. However, the percentage of females diagnosed during this same time frame found that 31.6% were HSV-2 positive/HSV-1 negative, a significant increase, whereas HSV-2 seropositivity declined significantly to 63.3%.[6]

Etiology

Most people are exposed to HSV-1 early in life, with more than half being positive for HSV-1 antibodies before 18 years and >90% of the population positive by age 70 years.[129] The infection is often asymptomatic and generally acquired through primary infection of mucocutaneous surfaces. The initial, primary disease is a gingivostomatitis characterized by vesicles in the oral cavity and, occasionally, an elevated temperature; life-threatening encephalitis or keratoconjunctivitis may also occur. Usually after primary exposure, HSV-1 enters cells of the trigeminal ganglion, where it may remain latent for the lifetime of the host.[130] Initial HSV-2 infections usually occur after puberty and coincide with the onset of sexual activity, although transfer to a neonate from an infected mother can occur. After primary infection, the virus enters a state of latency in the sacral dorsal root ganglia in many infected individuals; a high percentage of infected persons may never manifest the disease clinically.[131],[132] In both HSV-1 and HSV-2 infections, reactivation can occur, even when circulating antibody and sensitized lymphocytes are present. Clinically, the lesions

periodically erupt usually at the same location, and the interval between episodes varies widely between individuals.

Epidemiology

Although herpes was recognized several thousand years ago, genital herpes was not described until the 18th century. Overall, the seroprevalence of genital herpes (HSV-2) in the United States has declined from 18% in 1999 to 12.1% in 2016; however, seroprevalence remains highest in non-Hispanic Blacks at ~40%.[6] Fifty million individuals are estimated to have HSV-2, making it one of the most common STDs in the United States.[2,6] In 2013, U.S. physicians saw >300,000 new patients presenting with genital herpes simplex, with nearly 20% of non-Hispanic White females and more than double that in non-Hispanic Black females seropositive in the United States.[6]

Demographic characteristics indicate that the risk of genital HSV-2 infection increases from 2% to 5% with one sexual partner, to between 19% and 37% in those with ≥10 partners. Other demographic characteristics that increase the risk of acquisition include Black non-Hispanic race (three to four times the prevalence of non-Hispanic Whites); female sex (twice the prevalence of males); and presence of other STDs (increases odds ratio for viral shedding to 3.1).[133] The time range from exposure to disease onset is ~4 days (range 2–12 days).[134] HSV-2 infection increases the risk of HIV acquisition by up to threefold, possibly due to the presence of open ulcers or lymphocytes at the site, which may aid transmission. Of recent concern, although the seroprevalence of HSV-1 in 14- to 19-year-olds has been reported to have declined by 23% from 1999 to 2010, other studies have found HSV-1 infections actually increasing in this age group as a result in part of not having protective HSV-1 antibodies at sexual debut.[6,135]

Signs and Symptoms

CASE 72-14

QUESTION 1: R.A., a 28-year-old, sexually active male, presents with painful penile lesions and tender inguinal adenopathy. The lesions are vesicular and limited to the scrotum, glands, and shaft of the penis. The onset of the lesions was preceded by a 1-week period of fever, malaise, headache, and itching. Viral culture result of the lesions was positive for HSV infection.

What is the typical course and clinical presentation of herpes genitalis in males and females? What subjective and objective clinical data in R.A. are compatible with herpes genitalis?

Most initial episodes of genital herpes are symptomatic. As illustrated by R.A., the symptoms usually start ~1 week after initial exposure, with prodromal signs of tingling, itching, paresthesia, or genital burning. The prodromal stage, which can last from a few hours to several days, is followed by the appearance of numerous vesicles. The vesicles eventually erupt, resulting in painful genital ulcers. The pain and edema associated with genital herpetic lesions, especially if they are infected secondarily, can be severe enough to result in dysuria and urinary retention. Bilaterally distributed lesions of the external genitalia are characteristic. The lesions usually are limited to the glands, corona prepuce, and shaft of the penis in males and to the vulva and vagina in females. However, lesions can occur on the buttocks, thighs, and urethra.[132],[133] Asymptomatic or mucopurulent cervicitis may occur in about 15% to 20% of females with primary HSV-2 infections.[136] Rectal and perianal HSV-2 infections are more common in MSM and immunocompromised individuals.[137] Symptoms may include anorectal pain and discharge, tenesmus, and constipation.

Prior infection may ameliorate the severity of the first episode of genital herpes but does not impact the rate of recurrence.[138] In primary infections, the local symptoms of pain, itching, and urethral or vaginal discharge last up to 14 days, with a complete disappearance of lesions in 3 to 6 weeks.[132],[139] The clinical course of primary herpes is presented in **Figure 72-5**. Most patients have minor symptoms or are asymptomatic and are often unaware of being infected; however, individuals are most infectious within the

first year of acquisition of the virus.[133],[140] Asymptomatic individuals may also intermittently shed virus particles to others, which represents the primary way genital HSV2 is spread.[2]

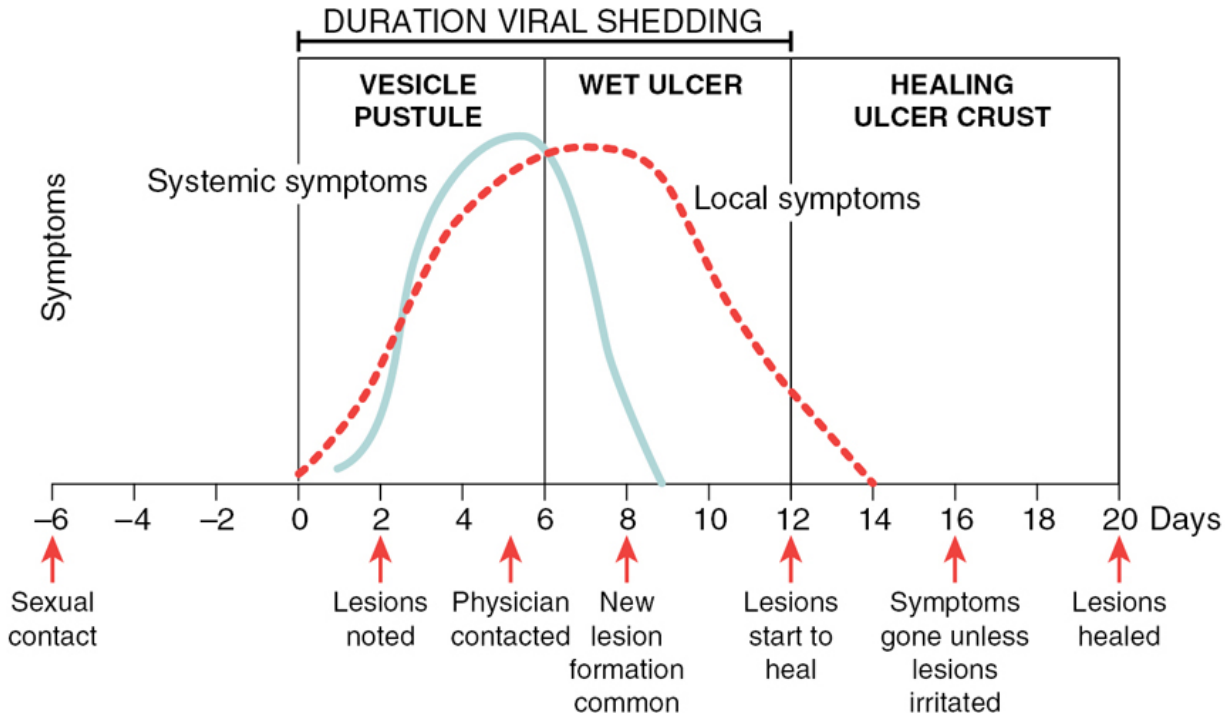

Figure 72-5 The clinical time course of primary genital herpes infections. (Adapted with permission of McGraw Hill LLC from Corely L, Wald A. Genital herpes. In: Holmes K, Sparling PF, Stamm WE, et al, eds. *Sexually Transmitted Diseases*. 4th ed. McGraw-Hill; 2008:399; permission conveyed through Copyright Clearance Center, Inc.)

Recurrence

CASE 72-14, QUESTION 2: Is R.A.'s infection likely to recur?

Most first-episode HSV-2 symptomatic patients experience a recurrence of their initial infection.[2] However, the rate of recurrent infections varies among individual patients. Approximately 38% can experience 6 or more episodes, and 20% can have >10.[139] Natural infection with HSV-2 induces type-specific immunity against

exogenous reinfection, but does not affect recurrences.[141] The severity of the primary episode and recurrence appear to be influenced by the host's immune status, especially a depressed T-cell response.[132] Recurrent infections usually appear at or near the site of the initial infection, and prodromal symptoms are reported by about 50% of persons with recurrent infection. Males experience recurrence more frequently than do females. In contrast with primary infections, there are fewer lesions and they are often unilateral.[132] Constitutional symptoms such as lymphadenopathy, fever, and malaise generally are also milder. Recurrent infections are also shorter in duration (average, 1 week); local symptoms such as pain and itching last 4 to 5 days and the lesions themselves last 7 to 10 days.[132] Although there is some variability, patients may have four to five recurrences during the first year, but reactivation frequency slowly declines over time.[133]

Transmission

Case 72-14, Question 3: R.A. states that this is the first time he has had such lesions and that he has had only one sexual partner for the past 14 months. His sexually active female partner has no history of herpes genitalis or any other STD. The couple is very curious as to how R.A. acquired his infection. How is HSV transmitted?

Transmission of HSV occurs by direct contact with active lesions or from a symptomatic or asymptomatic person shedding virus at a peripheral site, mucosal surface, or secretion.[142] Genital HSV-2 infections usually are acquired through sexual (vaginal or anorectal) intercourse, whereas genital HSV-1 infections are acquired through orogenital sexual practices. Consistent condom use has been shown to result in a 30% reduction in the risk of acquiring HSV-2, but there does not appear to be any differences in effectiveness between males and females. However, for every 25% of the time that condoms are used during vaginal or anal sex, the risk of HSV-2 acquisition decreases by 7%.[143] Regardless, patients with

seropositive HSV should be counseled to practice safer sex, using male or female condoms, at all times, not just during symptomatic episodes.[144]

A patient with genital herpes is contagious only when shedding the virus. The patient begins to shed virus during the prodromal phase, which may be several hours to days before the actual lesions first appear. Patients can, however, be asymptomatically diagnosed by serology and subsequently develop clinical lesions or be symptomatic on diagnosis and have recurrent episodes of clinical lesions. Symptomatic viral shedding occurs twice as often than in asymptomatic HSV-2 seropositive individuals, but subclinical viral shedding (ie, no lesions present) still occurs ~10% of days, regardless of gender.[145],[146] From a public health standpoint, unrecognized subclinical shedding may indicate a greater need for serologic testing to reduce further transmission and initiate therapy; however, it may also result in high false-positive rates and cause psychosocial harms.[147] Lesions are most contagious during the ulcerative phase. The median duration of viral shedding, as defined from onset to the last positive culture result, is about 12 days.[132] The mean time from the onset of vesicles to the appearance of the crust stage (~10.5 days) correlates well with the duration of viral shedding. However, there is considerable overlap between the duration of viral shedding and the duration of crusting. Females require a longer healing time than do males, 19.5 and 16.5 days, respectively.[132] The mean duration of viral shedding from genital lesions is 11 to 12 days following a primary infection and 4 days following a recurrent infection.[145] Therefore, patients should be advised to refrain from sexual activity until the lesions have completely healed; however, subclinical viral shedding may also transmit HSV-2.

A genital herpes infection may be acquired from an individual who has never had symptomatic genital lesions. States of asymptomatic or subclinical viral shedding occur in the majority of females with recurrent genital herpes as a result of reactivation of latent infection. These recurrent infections can have a primary disease presentation, causing the patient to blame the most proximate sexual partner when, in actuality, the exposure could have occurred in the distant

past.[148] Serologic and virologic typing can be used to determine whether this is a true primary infection. Sensitive detection techniques such as PCR may detect the presence of HSV; however, the relationship between a PCR-positive HSV test result and true communicability has yet to be fully determined because shedding can be intermittent.[149–151] In addition, asymptomatic spread can occur from multiple anatomic genital sites and in a bilateral manner, even with previous outbreaks of unilateral lesions.[152]

Diagnostic Tests

Case 72-14, Question 4: Viral culture result was negative for R.A., but HSV-2 point-of-care (POC) serology finding was positive for both R.A. and his sexual partner. How should these laboratory tests be interpreted?

The accuracy with which herpes genitalis can be diagnosed without the aid of laboratory tests generally is difficult to achieve, especially if the infection is not symptomatic. Thus, because of the potentially severe psychological and physiologic ramifications of such a diagnosis, either virologic and/or serologic confirmation of the diagnosis may be obtained.

The laboratory diagnosis of HSV-1 or HSV-2 infection depends on isolation of the virus using viral culture, whereas HSV DNA detection by PCR is more expensive than is viral culture and may not be as widely available for HSV antigen detection using ELISA (enzyme-linked immunosorbent assay) or DFA. Both PCR and ELISA can differentiate HSV-1 from HSV-2. Currently, HSV DNA PCR is the most sensitive method for detecting mucocutaneous herpes simplex infection rather than is simple viral culture in those with genital ulcers and is the preferred method for CSF samples.[151] Tests that measure serologic response or antibody production are valuable in documenting primary infection, but they are not useful in recurrent infections or determining when the initial infection occurred. It is possible to differentiate between antibodies to HSV-1 and HSV-2 by means of type-specific serologic assay. POC devices using HSV-2–

specific antibody testing kits offer ease, reduced time, differentiation between HSV-1 and HSV-2, and high sensitivities and specificities.[15,153,154]

Viral culture is more likely to yield false-negative results than do other testing methods because sensitivity is low.[2] A better antigen detection test could have been used, such as an ELISA or DFA. The lack of a positive viral culture result does not rule out the diagnosis of a primary infection in R.A., especially because the antibody test result was positive. The fact that R.A.'s partner's antibody test result was positive without a history of symptomatic disease suggests a distant infection with asymptomatic shedding.

Treatment

Case 72-14, Question 5: How should R.A.'s lesions be managed? Because the likelihood of recurrence of genital herpes is high, what treatment and prevention measures are recommended currently?

A diagnosis of genital herpes is concerning because there is no cure for the condition. Therapies ranging from antiviral agents to photoinactivation to investigational vaccines to supplements have been tried. Currently, only acyclovir (ACV), famciclovir (FCV), and valacyclovir (VCV) are approved agents for the treatment of symptomatic genital herpes and suppression of latent infection

The ideal anti-HSV agent should prevent infection, shorten the clinical course, prevent the development of latency, prevent recurrence in patients with established latency, decrease transmission of disease, and eradicate established latent infection.[132] To date, no agent has been successful in achieving all of these goals.

All three agents, ACV, FCV, and VCV, are effective for the short-term treatment of some HSV infections. ACV, a nucleoside analog, is a substrate for HSV-specific thymidine kinase. Through a series of phosphorylation steps, ACV is transformed to ACV-triphosphate, a competitive inhibitor of viral DNA polymerase. ACV has potent in

vitro activity against both HSV-1 and HSV-2, but it is far less active against varicella-zoster and CMV.[155] FCV, a prodrug of penciclovir, has increased oral bioavailability compared with acyclovir. Once converted in the intestine and liver to the active form, penciclovir, it is quickly phosphorylated in HSV in a manner similar to that of ACV. VCV is the L-valyl ester prodrug of ACV. The oral bioavailability of VCV is also significantly better than that of ACV, producing plasma levels of ACV comparable to those attained with IV-administered ACV, often eliminating the need for parenteral therapy.[156] All three antiviral drugs are equally effective for genital herpes infections.

IV ACV has been shown to reduce the median number of symptomatic days and duration of lesions.[157] Similar findings have been shown in the immunocompromised patient population.[158] IV and oral ACV or VCV also prevent HSV reactivation in seropositive immunocompromised patients who are undergoing bone marrow transplantation.[159] For patients with HIV, ACV 400 to 800 mg PO two to three times daily, FCV 500 mg twice daily, or VCV 500 mg twice daily for 5 to 10 days has been used for daily suppressive therapy.[2] Currently, IV therapy is recommended only for patients with severe genital or disseminated infections (eg encephalitis) who cannot take oral medications.

Topical ACV has minimal effect on the duration of symptoms in first-episode primary genital herpes, has low-quality evidence supporting its use, and is therefore not recommended for primary genital herpes.[157] Penciclovir 1% cream applied every 2 hours while awake for 4 days is an effective treatment option for herpes simplex labialis, but it is not currently indicated for genital herpes infections.

Oral antivirals speed the healing and resolution of symptoms of first and recurrent episodes of genital HSV-2 infections.[133] Treatment of primary infection after the first week of infection does change the natural history of recurrent outbreaks; thus, patients should be educated about the risk of sexual transmission, and prompt recognition of signs and symptoms and the early use of antivirals.[2],[160] The frequency of recurrence decreases with time in most patients. Recurrent episodes of genital HSV-2 infection can be

treated with any of the three available oral antivirals (**Table 72-8**). Rather than having to go into clinic, patients with recurrent infections could instead be provided with a supply of antiviral medication with them to allow early initiation of therapy, which may abort or reduce symptoms by 1 to 2 days.[161],[162]

Table 72-8
Antiviral Chemotherapy of Genital HSV-2 Infections

	Acyclovir	Valacyclovir	Famciclovir	Duration	Comments
First clinical episode	400 mg PO tid *or* 200 mg PO five times per day	1 g PO bid	250 mg PO tid	7–10 days	May extend treatment duration if healing is incomplete
Episodic recurrent infection	400 mg PO tid *or* 800 mg PO bid or 800 mg PO tid × 2 days	1 g PO QD *or* 500 mg PO bid × 3 days	125 mg PO bid or 1 g PO bid × 1 day or 500 mg PO × 1, then 250 mg bid × 2 days	5 days	Most effective if initiated within the first 24 hours of onset of lesions or during the prodrome
Daily suppressive therapy	400 mg PO bid[a]	500 mg PO QD[b] or 1 g PO QD	250 mg PO bid	Daily	Reduces the frequency of genital herpes recurrences by ≥75% among patients who have frequent recurrences (ie, ≥6 recurrences per year); use should be reevaluated at 1 year
Severe disseminated	5–10 mg/kg IV Q 8 hours	Not indicated	Not indicated	2–7 days[c]	Hospitalize and treat until clinical resolution of symptoms. Follow-up IV therapy with PO ACV to complete 10 days
HIV-infected: episodic	400 mg PO tid *or* 200 mg 5/day	1 g PO bid[d]	500 mg PO bid	5–10 days	Treat until clinical resolution of lesions
HIV-infected: suppressive	400–800 mg PO bid or tid	500 mg PO bid[e]	500 mg PO bid		

Note: Regimen recommendations derived from the 2021 Centers for Disease Control and Prevention (CDC) Recommendations.[2]

ACV, acyclovir; bid, twice a day; HIV, human immunodeficiency virus; IV, intravenous; PO, orally; tid, three times a day; QD, on prescription.

[a]Safety and efficacy of up to 6 years have been documented with the use of acyclovir.

[b]Valacyclovir 500 mg on prescription (QD) seems less effective in patients with >10 episodes per year. Thus, 1 g QD should be used in these patients.

[c]Or until clinical improvement is observed.

[d]Dosages up to 8 g/day have been used, but an association with a syndrome resembling either hemolytic uremic syndrome or thrombotic thrombocytopenic purpura was observed.

[e]Effective in decreasing both the rate of recurrences and the rate of subclinical shedding among HIV-infected patients.

Source: Adapted from Workowski KA, Bachmann LH, Chan PA, et al. Sexually transmitted infections treatment guidelines, 2021. *MMWR Recomm Rep*. 2021;70(4):1–187. doi:10.15585/mmwr.rr7004a1.

Daily suppressive therapy with ACV, FCV, or VCV reduces the frequency of recurrent episodes up to 70% to 80% among patients with frequent (eg, five to eight episodes per year) genital herpes.[2,163] Recurrent outbreaks diminish with time; thus, after each year of continuous suppressive therapy, an effort should be made to discuss discontinuing therapy with the patient. The use of suppressive therapy does not eliminate viral transmission. However, a randomized, controlled clinical trial of serodiscordant HSV-2–positive couples found a statistically significant decrease in the rate of transmission to the uninfected partner when the infected partner took VCV 500 mg QD.[164] In such couples, suppressive therapy should be considered to help prevent transmission, in addition to condom use and refraining from sexual activity during recurrences. The CDC recommends various dosing regimens for VCV; however, one meta-analysis found a consistent prophylactic benefit if VCV was dosed at 250 mg twice daily or 500 mg once daily.[165] Immunocompromised patients may require higher doses or more frequent intervals for suppression.[166]

Most cases of ACV-resistant HSV occur in the immunocompromised host; however, the resistance is <5%.[167] All ACV-resistant strains are also resistant to VCV, and most are resistant to FCV as well. Foscarnet 40 to 80 mg/kg IV every 8 hours or cidofovir 5 mg/kg once weekly until clinical resolution may be used for severe ACV-resistant genital HSV infections.[2] Cidofovir 1% gel (not commercially available in the United States) applied once daily for 5 days may be an alternative for mucocutaneous HSV resistant to ACV, but more studies are needed.[2,168]

R.A. is not yet a candidate for daily suppressive ACV therapy. A summary of the indications for ACV, FCV, and VCV is outlined in Table 72-8.

ADVERSE EFFECTS

Case 72-14, Question 6: What adverse effects associated with ACV, FCV, or VCV should be anticipated?

Overall, all forms of ACV, including VCV and FCV, are associated with relatively few adverse reactions largely because of the drugs' affinity for viral thymidine kinase over cellular kinase.

Hematuria and an increase in blood urea nitrogen and serum creatinine may occur, primarily in patients with underlying renal disease or in those receiving concomitant nephrotoxic agents. However, this complication is almost entirely associated with the IV route. In addition, severe local reactions are possible with IV administration. In patients with HIV/AIDS, VCV at a dosage of 8 g/day was associated with a hemolytic uremic syndrome or thrombotic thrombocytopenic purpura-like syndrome. However, this complication has not been observed with normal therapeutic doses. As described previously, when given as IV in high doses or with significant dehydration, ACV crystallizes in the renal collecting tubules of animals, leading to renal insufficiency.[169] ACV should not be rapidly infused or administered at concentrations >10 mg/mL. Dose adjustment is necessary for all three antiviral agents in patients with decreased renal function.

Although neurotoxicity is a rare side effect, case reports of coma and delirium have been reported in patients with renal failure.[170,171]

IV ACV occasionally has been associated with cutaneous irritation and phlebitis, reversible leukopenia,[172] and transient elevations of liver transaminases. Oral ACV and VCV are relatively safe and do not produce any serious side effects at normal doses. Patients receiving oral ACV, VCV, or FCV may experience nausea, dizziness, diarrhea, and headaches.

Patient Education and Counseling

Case 72-14, Question 7: What are the roles for education and counseling in patients with genital herpes? Are other forms of local or symptomatic care useful?

Most genital herpes infections are benign, and lesions heal spontaneously unless the patient is immunocompromised, or the lesions have become infected secondarily. The patient should be instructed to keep the affected areas clean and dry. To prevent autoinoculation, the patient should be told not to touch the lesions and to wash hands immediately afterward if they come in contact with the lesion. Local anesthetics provide relief from the pain of genital lesions, but they should be avoided if possible because they counteract efforts to keep the lesions dry. Local corticosteroid therapy is contraindicated because it may predispose the patient to secondary infections.

Patient counseling should include the source contact and any future partner. Health care practitioners should attempt to relieve patients' feelings of guilt and anxiety; discussion of long-term consequences should take place after the acute symptoms of the infection have resolved.

For individuals with frequent recurrences, efforts should be made to identify and avoid stimulatory factors such as sunlight, trauma, or emotional stress. The limitations of therapy and the decreased severity and frequency of recurrences with time should be explained to the patient. The periods of infectivity and the need to avoid sexual activity even when lesions are not present should be emphasized, indicating the need for continuous barrier protection during sexual intercourse. Females with herpes genitalis should be scheduled for routine Pap tests and be instructed to discuss their HSV with their physicians if they become pregnant.

Currently, there is no completely effective way to prevent the transmission of HSV-2 infection. Barrier forms of contraception, in particular condoms, may reduce the transmission of HSV, but this may be limited only to male-to-female transmission owing to the large area that herpes lesions may occupy on the female.[173] However, greater use of condoms by males can increase protection and is recommended to prevent HSV infections.[174] Nonoxynol-9, a spermicide that has in vitro anti-HSV activity, is ineffective in the prevention of established genital HSV infection and may actually

increase the risk of transmission of HSV by causing genital ulceration.[175] Herpes simplex vaccines have been extensively studied,[176] but no candidate vaccine has been submitted for approval.

Complications

CASE 72-15

QUESTION 1: M.F. is a 23-year-old, sexually active female student with a history of frequent and severe recurrences of genital herpes since her initial infection 3 years ago. M.F. has tried numerous therapies, including suppressive and episodic antivirals. None of these therapies has provided M.F. with any relief of her symptoms, nor have they decreased the frequency of her recurrences. M.F. has read much in the lay press about herpes and is concerned about the possible complications of the disease, especially cervical cancer.

What are the potential complications of herpes genitalis?

Previous research suggested that HSV-2 might be an oncogenic agent responsible for carcinoma of the cervix. However, a large longitudinal nested case–control study using nearly 20 years of seroepidemiologic and epidemiologic data combined with a meta-analysis concluded that it is very unlikely that HSV-2 is associated with the development of invasive cervical carcinoma.[177] Severe complications of herpes genitalis include meningitis and encephalitis as well as disseminated disease.[2,132]

PREGNANCY

CASE 72-16

QUESTION 1: A.P., a 26-year-old female in her 32nd week of gestation, was hospitalized with painful genital lesions, headache, fever, increased vaginal discharge, and dysuria of 1 week's duration. Multiple ulcerative lesions consistent with genital herpes were present on the cervix, vulva, labia minora, and thighs.

How should A.P. be treated?

Herpes genitalis seropositivity in pregnant females occurs more frequently than in nonpregnant females, with 20% to 30% of all pregnant females having serologic evidence of HSV-2 infection.[178] When HSV is acquired by the mother near the time of delivery, transmission to the neonate can be 30% to 50%, but it is <1% in those who acquired it early in pregnancy or had recurrent infection.[2] Unfortunately, a large proportion of those infections occurring during pregnancy are limited to the cervix and are totally asymptomatic, often eluding diagnosis.

Pregnant patients with a history of recurrent genital herpes should be examined carefully when they present in labor for evidence of active disease. The safety of systemic ACV, VCV, and FCV in pregnant females has not been established in controlled trials, but the CDC cites the lack of documented fetal harm to assert that ACV can be used safely in all stages of pregnancy (and during breast-feeding).[2] Thus, it is reasonable to recommend ACV to treat HSV in this patient and possibly VCV and FCV because of data from animal trials showing a low risk in pregnancy, although the data are limited.[2] Some small studies suggest ACV administered for several weeks before delivery may decrease recurrent outbreaks and lessen the need for herpes-related cesarean section,[179] whereas a larger randomized clinical trial did not show a benefit in reducing the need for a cesarean delivery with primary infection.[180] In general, it does seem that patients with symptomatic genital herpes benefit from cesarean section.[181] The manufacturer of Zovirax® (ACV) maintained an extensive database of fetal complications related to ACV use that showed no link between ACV and birth defects has been established.[182] The decision to treat HSV with ACV during pregnancy should depend on the clinical severity of infection. If the mother has an active herpes genitalis infection at the time of delivery (either active genital lesions or HSV-2 cervicitis) or is experiencing a recurrent, the baby should be delivered by cesarean section to help minimize the risk of exposure to the newborn. However, if no genital lesions are present at the time of labor, vaginal delivery may be recommended.[2] There is evidence that up to 70% of neonatal herpes cases occur in asymptomatic females and the use of ACV or VCV

after 36 weeks gestation may decrease clinical disease and viral shedding to the fetus.[183]

Neonatal herpes is a devastating systemic infection of the newborn, associated with high morbidity and mortality, especially when infected with HSV-2 versus HSV-1.[184] HSV is usually transmitted to the newborn during passage through an infected birth canal, ~300 times greater than when HSV is not present.[181] The risk of transmission to the newborn is greatest in mothers who acquire an initial infection late in the third trimester and lower in mothers with recurrent infection or those who acquire herpes in the first trimester (25% –50% vs <1% for preexisting infection).[184]

GENITAL WARTS

CASE 72-17

QUESTION 1: S.L., a 21-year-old female, presents to the health clinic for her annual examination. One week later, her Pap test result is read as low-grade squamous intraepithelial lesion (LGSIL) with koilocytosis. A colposcopy is subsequently performed, revealing changes consistent with cervical flat warts, and biopsy finding of the lesion reveals low-grade cervical intraepithelial neoplasia (CIN).

What is the cause of S.L.'s infection? How should she be managed?

HPV is the cause of genital warts or condylomata acuminata. Types 6 and 11 account for >90% of genital warts. Other types of HPV, including 16 and 18, account for 66% of cervical cancer in the United States.[6] They are associated with changes in Pap test findings, including koilocytosis and cervical dysplasia. In the United States, the seroprevalence of any HPV serotype causing genital infection is 42.5% among adults 18 to 59 years of age; however, prevalence is significantly higher in sexually active non-Hispanic White and Black males.[185],[186]

CIN is a common cervical cancer grading system using histologic changes to classify specimens in three categories, CIN-1, -2, and -3.

The higher the number, the greater is the chance of progressing to invasive cervical cancer. Most new cases of HPV infection spontaneously regress, but with progressive histologic changes, the chance of spontaneously regressing diminishes (CIN1, 60%; CIN2, 30%; and CIN3, 10%).[187] Types of HPV are also classified as high risk, or those likely to cause cancer, and low risk, those less likely to cause cancer. HPV types 16, 18, 31, 33, 45, 52, and 58 are considered high risk and types 6 and 11 are low risk, the latter mostly resulting in genital warts. In females, visible warts occur on the labia, introitus, and vagina. Subclinical lesions also commonly occur on these sites and on the cervix, as in S.L.'s case. They are visible only by colposcopy after applying acetic acid. Males can sexually transmit HPV infections to females as well as exhibit genital warts, and anal and penile cancers are associated with oncogenic HPV types, especially type 16.[188] The goal of HPV therapy is the removal of symptomatic warts. Several therapeutic options are available and include patient-administered treatments to visible warts such as podofilox 0.5% solution or gel, imiquimod 3.75% or 5% cream, and sinecatechins 15% ointment; provider-administered therapies include topical treatments (bichloroacetic or trichloroacetic acid 80%–90%, cryotherapy) and surgical removal (laser or excision).[2] However, it is important to note that none of these treatments can eradicate HPV infection or alter the natural history of HPV. It is important to individualize therapy, considering location and number of warts, patient preference, cost, and convenience.

Podophyllin resin, compounded as a 10% to 25% solution in tincture of benzoin, can be applied by the health care provider to visible warts; however, this is generally no longer recommended because of severe systemic toxicity if the resin is applied to large surface areas and not washed off after 4 hours of application.[2] Podophyllin is potentially neurotoxic if absorbed in large amounts. In addition, the rate of wart recurrence after podophyllin therapy is also extremely high, around 50%. As an alternative to podophyllin resin, podofilox 0.5% solution or gel, the active component of podophyllin resin, may be applied by the patient (after the health care provider demonstrates proper application technique) with a cotton swab, or

podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. A total of four cycles, 0.5 mL/day, or application of an area >10 cm^2 should not be exceeded. Podofilox solution is not suitable for use with perianal warts; the gel is more practical for this region. Podofilox has the advantage over podophyllin resin in that it has a longer shelf life, does not need to be washed off, and has less systemic toxicity.[189] However, it should still be applied in limited doses and should also be avoided in pregnancy.

Imiquimod induces cytokines and activates the cell-mediated immune system. In initial trials, complete clearance of warts took place in 37% to 50% of immunocompetent patients, but up to 20% experienced recurrence.[190] The 5% cream is optimally applied by finger at bedtime three times per week and the 3.5% cream once daily for up to 16 weeks.[191],[192] It is usually left on for 6 to 10 hours before it is washed off with soap and water. Imiquimod may take as long as 8 weeks before the warts are cleared. Mild-to-moderate local irritation occurs in more than half of the patients who use it, especially when used daily instead of three times weekly as directed. The cream may weaken condoms and diaphragms.

Sinecatechins are green-tea extracts that contain active catechins with purported immunostimulatory, antiproliferative, and antitumor properties. There are limited data on this product, but it may be more effective than is imiquimod or podofilox by clearing up to 55% of external genital warts.[193] A 15% topical solution can be applied by finger directly to the wart three times a day up to 16 weeks, with the most common side effects being local erythema, pruritus, burning, and pain. Individuals who are immune suppressed, have genital herpes, or are pregnant should not use sinecatechins because their safety and efficacy have not been fully evaluated.[2]

Cryotherapy by application of liquid nitrogen can be more effective than is podophyllin but requires special equipment and trained personnel. Pain and skin blistering after treatment is common. Cryotherapy is associated with minimal systemic toxicity and is useful against oral, anal, urethral, and vaginal warts.

Trichloroacetic acid (80%–90%) is used topically in the treatment of some genital warts, but its efficacy is uncertain. To date,

interferons are not recommended because of expense and toxicity. Cases refractory to topical drug therapy should be considered for surgical treatment.

Prevention

Prevention and control of STDs have largely revolved around education and antimicrobials. Immunization, however, holds the promise of protecting large numbers of people before they are at risk for STDs as well as targeting those who already have the infection. Hepatitis B is an example of an STD with a highly effective vaccine that is now mandatory for school-aged children.

In 2006, the first vaccine to prevent HPV types 6, 11, 16, and 18 was approved in the United States. This quadrivalent vaccine was tested in females from 15 to 26 years of age and demonstrated 98% to 100% protection against HPV types contained in the vaccine.[194,195] In males, the quadrivalent vaccine efficacy was 62.1% to 89.4% against genital warts, depending on previous HPV exposure, leading to its approval for males and boys 9 to 26 years old.[196] Using bridging data, it is estimated that 99% to 100% of 9- to 15-year-olds will seroconvert. In 2014, a 9-valent HPV vaccine was approved to replace the discontinued quadrivalent vaccine. The extra five types (31, 33, 45, 52, and 58) add 15% more cervical cancer coverage protection to the 66% covered by types 16 and 18 in the quadrivalent.[197] The 9-valent HPV vaccine can be administered as a two-dose series as early as age 9 years, but is CDC recommended at 11 to 12 years as part of a routine adolescent health care visit (and ideally before the commencement of sexual activity). If this vaccine is administered past age 15 years, then it needs to be administered as the usual three-dose series instead. Because there are >30 types of HPV associated with anogenital disease, a previous HPV infection is not a contraindication to vaccination. Although the HPV vaccine may be of minimal benefit to older individuals, it may still be recommended and administered on an individual basis to adults ages 27 to 45 years who may not be adequately vaccinated

under a shared clinical decision model. It is also important to note that receipt of the HPV vaccine does not change the recommendation for Pap tests. Lastly, it should not be considered as a therapeutic option because it has no impact on active HPV infection.

Osteomyelitis and Septic Arthritis

Jacqueline L. Olin, Linda M. Spooner, and Karyn M. Sullivan

CORE PRINCIPLES		CHAPTER CASES
OSTEOMYELITIS		
1	Acute hematogenous osteomyelitis is characterized by the abrupt onset of localized pain and tenderness at a single site, fever, and increased inflammatory markers (erythrocyte sedimentation rate, C-reactive protein). Imaging techniques and blood and bone cultures (if done) may reveal findings consistent with bone changes in osteomyelitis and the responsible pathogen.	**Case 73-1 (Questions 1, 2), Table 73-1**
2	Initial empiric antibiotic therapy for acute hematogenous osteomyelitis should be	**Case 73-1 (Question 3), Table 73-2**

	directed at gram-positive cocci, including methicillin-resistant *Staphylococcus aureus* (MRSA). Protein binding and bone concentrations of antibiotics are not critical factors in predicting successful treatment, as long as the responsible pathogen is susceptible to the chosen therapy, and treatment is given in high doses for a long duration.	
3	If blood or bone cultures grow the likely pathogen, then therapy should be de-escalated when possible based on organism susceptibilities. Assuming no allergies, methicillin-sensitive *Staphylococcus aureus* (MSSA) should be treated with oxacillin or nafcillin. The overall duration of therapy (by intravenous [IV] route and possibly orally) should be at least 4 weeks.	**Case 73-1 (Questions 4–6), Tables 73-2, 73-3**
4	Osteomyelitis associated with a contiguous focus of infection typically occurs after trauma and the consequent orthopedic corrective surgery. Common symptoms are pain, tenderness, erythema, and drainage at the site of injury or infection. Imaging studies usually show bone changes consistent with infection. It is often polymicrobial.	**Case 73-2 (Question 1), Table 73-1**
5	With contiguous osteomyelitis, surgical efforts should be instituted to reassess the site of bone injury and infection, with deep tissue or bone samples obtained	**Case 73-2 (Questions 2, 3)**

	for culture. Treatment is IV therapy for at least 4 weeks, and the antibiotics chosen should depend on the cultured organisms and their antibiotic susceptibilities.	
6	Osteomyelitis associated with vascular insufficiency most often occurs in patients with diabetes mellitus. Neuropathy and impaired blood flow are risk factors for the development of chronic lower extremity cellulitis and underlying osteomyelitis. Multiple gram-positive and gram-negative aerobic and anaerobic bacteria may be involved; an initial empiric treatment typically includes vancomycin and an antipseudomonal β-lactam. Definitive therapy is based on the results of deep surgical cultures. Duration of treatment should be 6 weeks, with chronic suppressive therapy considered thereafter.	**Case 73-3 (Questions 1, 2)**
7	Chronic osteomyelitis can present years later at a site of previous bone infection and is usually characterized by a draining sinus tract from bone to skin. Chronically infected dead (necrotic) bone needs to be surgically removed when possible. Chronic osteomyelitis is often polymicrobial, and the same organism (especially *S. aureus*) that was causative of a previous bone infection could still be involved in	**Case 73-4 (Questions 1–4)**

	chronic infection. High-dose IV therapy directed at the results of bone culture and the sensitivity results for 6 weeks is recommended to offer the best chances of preventing the extension of infection to the adjacent uninfected bone.	
8	Orthopedic implant–associated infections with adjacent bone osteomyelitis usually require surgical removal of the infected prosthesis for cure. Antibiotics should be directed at the cultured bacteria from a joint aspirate or from deep surgical specimens. The most common pathogens are *S. aureus* and coagulase-negative staphylococci. If the prosthesis cannot be totally removed, lifelong, chronic suppressive oral therapy may be necessary.	**Case 73-5 (Questions 1–3)**
	SEPTIC ARTHRITIS	
1	Nongonococcal septic arthritis is characterized by fever and the acute onset of joint pain and effusion in a single joint. Infection is typically acquired hematogenously from an originating site that may not always be easily identified. *S. aureus* is the most common pathogen. Duration of treatment should be 6 weeks, with oral therapy for the final 2 weeks.	**Case 73-6 (Questions 1, 2)**
2	*Neisseria gonorrhoeae* is the most common cause of polyarticular arthritis	**Case 73-7 (Questions 1–3)**

in a young, sexually active adult. Skin lesions may also be present in disseminated gonococcal infection (DGI). The diagnosis is frequently based on the clinical syndrome and sexual history because joint fluid aspirate and blood culture results are frequently negative. IV ceftriaxone is the treatment of choice and should be continued for 1 to 2 days after improvement begins. Treatment duration is 7 to 14 days.

INTRODUCTION

Osteomyelitis is an inflammation of the bone marrow and surrounding bone associated with infection. Any bone can be involved, and substantial morbidity is possible even with early diagnosis and treatment. Despite the continued refinement of diagnostic procedures (eg, radionuclide imaging, computed tomography, magnetic resonance imaging), advances in antimicrobial therapy, and the use of prophylactic antibiotics before orthopedic procedures, osteomyelitis continues to be difficult to cure.

Osteomyelitis can affect all age groups. The most common causative microorganisms of acute osteomyelitis have historically been streptococci and staphylococci. *Staphylococcus aureus* remains the most causative organism, accounting for >50% of all cases, although the prevalence of infection caused by methicillin-resistant *Staphylococcus aureus* (MRSA) is increasing across all age groups. In addition, osteomyelitis caused by gram-negative and anaerobic bacilli is becoming more common.[1]

Bone may be infected by three routes: hematogenous spread of bacteria from a distant infection site, direct infection of bone from an adjacent or contiguous source of infection, and infection of bone

secondary to vascular insufficiency. **Table 73-1** summarizes characteristics associated with osteomyelitis.[1–3] Patients with recurrent osteomyelitis are considered to have chronic osteomyelitis.

Table 73-1
Features of Osteomyelitis

Feature	Hematogenous	Adjacent/Contiguous Site of Infection	Vascular Insufficiency
Usual onset: pediatric or adult	Predominantly pediatric	Adult	Adult
Sites of infection	Tibia, femur (children); vertebrae (adults)	Femur, fibula, tibia, skull, mandible	Foot
Risk factors	Bacteremia	Surgery, trauma, cellulitis, joint prosthesis	Diabetes, peripheral vascular disease
Common bacteria	*Staphylococcus aureus*, gram-negative bacilli; usually *one* organism	*S. aureus*, streptococci, gram-negative bacilli, anaerobic organisms; often *polymicrobial*	*S. aureus*, coagulase-negative staphylococci, streptococci, gram-negative bacilli, anaerobic organisms; often *polymicrobial*
Clinical findings	Fever, chills, local tenderness, swelling; limitation of motion	Fever, warmth, swelling; unstable joint	Pain, swelling, drainage, ulcer formation

Bone Anatomy and Physiology

The bone is divided into three sections: the epiphysis, located at the end of the bone; the metaphysis (adjacent to the epiphysis and part of the epiphyseal growth plate); and the diaphysis (midsection of the bone). Surrounding most of the bone is a fibrous, cellular envelope. The external portion of this envelope is the periosteum, and the internal portion is the endosteum.

Blood vessels that supply bone tissue and support bone growth are located predominantly in the epiphysis and metaphysis of the bone. Nutrient arteries enter the bone at the metaphyseal side of the epiphyseal growth plate and lead to capillaries that form sharp loops within the growth plate. These capillaries lead to large sinusoidal veins that eventually exit the metaphysis through a nutrient vein. Within the sinusoidal veins, blood flow is slowed considerably, and infection is possible with bacterial colonization.[4]

Differences in the vasculature of bone in different age groups lead to different forms of osteomyelitis. In neonates and adults, vascular communications are present between the metaphysis and epiphysis, which can allow infection to spread from bone to the adjacent joint.

During childhood, however, this area often is protected from infection because the epiphyseal plate separates the vascular supply for these two regions.[4]

Hematogenous Osteomyelitis

Hematogenous osteomyelitis predominantly occurs in prepubertal children but may be seen in older adults, patients with indwelling central catheters, and intravenous (IV) drug users.[1] Osteomyelitis in children tends to be acute, hematogenous, and often responsive to antibiotic therapy alone. It can be difficult to identify all pathogens.[5] In comparison, osteomyelitis in adults tends to be subacute or chronic; commonly results from trauma, infection of prosthetic devices, or other insult; and often requires surgical debridement in addition to antimicrobial therapy.[1–3]

Hematogenous infection in children develops primarily in the metaphysis of the rapidly growing long bones of the body, usually with a single focus in the femur and tibia, where the slowed blood flow allows bacteria to colonize and multiply. Hematogenous osteomyelitis in neonates is an especially serious disease that often involves multiple bones, especially the long bones. The acute infectious process (eg, edema, inflammation, small vessel thrombosis) increases bone pressure, which compromises blood flow and eventually leads to necrosis. Released cytokines alter bone integrity by promoting osteoclast activity. Eventually, the elevated pressure and necrosis cause devitalized bone to fragment from healthy bone (sequestra). With continued spread of the infection into the outer layers of the bone and soft tissue, abscess and draining sinus tracts may form.[1,3]

Rapid infection spreading across the epiphyseal plate to the adjacent joint can lead to septic arthritis, necessitating immediate and aggressive treatment. Vertebrae involvement is seen more frequently in adults.[1–3]

The most common organism causing hematogenous osteomyelitis is *S. aureus*, responsible for up to 85% of pediatric cases.[4] The

emergence of both hospital- and community-associated strains of MRSA has challenged the management of osteomyelitis. MRSA infections are associated with an increased risk of antibiotic treatment failures and complications, including abscess formation, deep vein thrombosis, and septic emboli.[6] The most common streptococcal pathogen for hematogenous osteomyelitis is *Streptococcus pyogenes.*[1] Gram-negative bacilli (*Escherichia coli*, *Klebsiella*, *Proteus*, *Salmonella*, and *Pseudomonas*) are responsible for an increasing number of cases of osteomyelitis as well. *Pseudomonas aeruginosa* is more commonly seen in patients with indwelling central catheters and in IV drug users, whereas *S. aureus* and *Salmonella* species are common causes in patients with sickle cell anemia.[1]

Clinical features of hematogenous osteomyelitis vary, depending on the patient's age and the infection site. In children, infection usually is characterized by an abrupt onset of high fever and chills, localized pain, tenderness, and swelling. Systemic symptoms often are absent in neonates, potentially delaying the diagnosis. A diagnosis, therefore, is based on localized symptoms such as edema and restricted limb movement. Systemic symptoms are also less common in adults, although patients with vertebral osteomyelitis can present with the insidious onset of localized back pain and tenderness.[1,3]

Acute Osteomyelitis

USUAL CLINICAL PRESENTATION

CASE 73-1

Question 1: L.D., a 7-year-old girl, is unable to go to school today because of fever and worsening leg pain. Her upper left leg started to hurt 3 to 4 days ago, and last night she began limping. Her parents report no history of trauma to the area. Her past medical history is significant only for two episodes of otitis media at ages 2 and 5. In the pediatrician's office, maximal tenderness is localized over the left distal femur without knee joint effusion. No signs of swelling,

warmth, or trauma are seen. Her white blood cell (WBC) count is 8000/μL with a normal WBC differential. Plain radiographic study findings of the left leg are normal, but the erythrocyte sedimentation rate (ESR) is 58 mm/hour (normal ≤30 mm/hour). Two blood samples are obtained for culture and sensitivity testing, and L.D. is sent home with directions for bed rest and use of acetaminophen as needed for fever. Two days later, she is admitted to the hospital with severe pain and tenderness in her left leg and a fever of 101.84 °F (38.8 °C). The blood cultures obtained 2 days ago are positive for *S. aureus*, with susceptibilities still pending. C-reactive protein (CRP) is 14 mg/dL (normal, <2 mg/dL). Another plain radiographic study finding is normal, but a magnetic resonance imaging (MRI) scan reveals inflammation in her left distal femur.

What findings in L.D. are consistent with hematogenous osteomyelitis?

L.D. displays the usual signs and symptoms of acute hematogenous osteomyelitis in children. She is a previously healthy child who experienced acute localized pain and tenderness of the left distal femur, abrupt onset of high fever, and an elevated ESR and CRP. Her plain radiographic study findings were normal on two occasions; however, destructive changes to bone often do not appear on plain radiographs for at least 10 to 14 days after onset of infection.[1] Hence, a normal plain film does not rule out acute osteomyelitis if obtained within the first 2 weeks of infection. Diagnosis includes radionuclide imaging (bone scans), computed tomography (CT), or MRI.[1,4] MRI is more sensitive than is CT for the assessment of soft tissue and detecting early bone marrow edema; however, it often requires sedation for children.[4] The sensitivity of bone scan detection of osteomyelitis has been lowest when the infection was caused by community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA).[4] L.D.'s MRI scan on hospitalization detected inflammation in the left distal femur. Although L.D. did not have a bone biopsy sent for culture, her clinical picture, a positive MRI scan result, and blood culture results positive for *S. aureus* establish the diagnosis of osteomyelitis. The specific event that caused bacteremia with dissemination to bone is unknown, as is often the case in children.[4]

Laboratory tests that should be routinely obtained in every child suspected of having osteomyelitis include a complete blood count (CBC), ESR, and serum CRP. Although these tests are not specific

for the diagnosis of osteomyelitis, they help confirm the clinical diagnosis. An increased WBC count is consistent with osteomyelitis, but leukocytosis is absent in many children with osteomyelitis at the initial examination. Thus, L.D.'s WBC count of 8000/μL is not unusual. In adults, leukocytosis is more common in an acute infection rather than with recurrent or chronic disease. Both ESR and CRP are nonspecific markers of systemic inflammation when elevated.

Predisposing factors for hematogenous osteomyelitis include any risk factors for bacteremia, for example, indwelling catheters such as hemodialysis shunts and chronic central venous catheters, IV drug use, and a distant focus of infection in the gastrointestinal or urinary tract. None of these factors exist in L.D. In children such as L.D. who have no history of trauma, fractures, or penetrating injury, the most common cause of acute hematogenous osteomyelitis is *S. aureus*, and the possibility of CA-MRSA must be considered.[1,6]

PATIENT WORKUP

CASE 73-1, QUESTION 2: What additional patient and diagnostic information should be obtained before L.D. receives her first dose of antibiotics?

Before L.D. receives antibiotic therapy, she should be assessed for drug allergies, especially penicillin allergy. Patient interviews, discussions with her parents, and a comprehensive review of her medical record are necessary, especially with a history of allergy. Details of an allergic reaction, including symptoms, onset of the reaction, probable causative agent, treatment, and exposure to related antimicrobials should be evaluated. Cultures of blood and bone aspirate material optimally identify the pathogen and must be part of the initial workup before the start of antibiotics. Cultures taken after initiation of antibiotics can decrease culture yield.[5]

In L.D.'s case, the positive blood culture and MRI findings establish the diagnosis of osteomyelitis. If the blood culture results had been negative, however, a bone aspirate would be

recommended to identify the pathogen.[1] Once material has been obtained for culture and sensitivity testing, empiric antibiotic therapy should start as soon as possible.

TREATMENT

Empiric antibiotic therapy

Case 73-1, Question 3: L.D. has no history of drug allergies. She took amoxicillin for the previous episodes of acute otitis media without incident. What empiric antibiotic(s) should be started? What is the relevance of bone concentrations or protein binding of antibiotics in the selection of therapy for osteomyelitis?

Treatment should be initiated as soon as possible to improve the chances for complete eradication of infection and to avoid the need for surgery. Thus, empiric antibiotic therapy is often administered while bacterial culture results are pending or before antibiotic susceptibility results are known. The chosen agent should be administered IV at high doses to optimize drug concentration in infected bone.

Even if culture results are pending or have returned negative results, the age of the child can predict the likely pathogen and guide empiric antibiotic selection. For example, *S. aureus* and *Streptococcus* species are commonly responsible for osteomyelitis in the neonate.[1] *Kingella kingae*, a facultatively anaerobic, gram-negative hemolytic bacillus, is being detected with increasing frequency in children younger than age 3 years, especially in the day care setting.[7] **Table 73-2** summarizes the common causative organisms of acute hematogenous osteomyelitis in children and recommended drugs and doses for treatment.[2,4,5,8–10]

Table 73-2

Empiric Intravenous Antibiotics for Acute Osteomyelitis in Children

Host	Likely Organisms	Antibiotics	Dose	
			(mg/kg/day)	(doses/day)
Neonate	*Staphylococcus aureus* Group B streptococci Gram-negative bacilli	Oxacillin (or nafcillin) *with* cefotaxime	25–50	2–4
			50	2–4
<3 years	*S. aureus*	Vancomycin *or*	40–60	4
		Linezolid *or*	30	3
		Daptomycin	6–10	1
	Haemophilus influenzae type b	Oxacillin (*or* nafcillin) *with* cefotaxime	150–200	4
			100–180	4–6
	Kingella kingae	Cefazolin *or*	100–150	3
		Ampicillin-sulbactam	100–200	4
≥3 years	*S. aureus*	Vancomycin *or*	40–60	4
		Linezolid		
		≤12 years	30	3
		>12 years *or*	600 mg dose	2
		Daptomycin *or*	6–10	1
		Oxacillin (or nafcillin) *or*	150–200	4
		Cefazolin *or*	60–150	3–4
		Clindamycin	40	3–4
	S. pyogenes	Cefazolin	60–150	3–4
After puncture wound through shoe	*Pseudomonas aeruginosa*	Ceftazidime	100–150	3
Child with sickle cell disease	*Salmonella* sp. *S. aureus*	Oxacillin (or nafcillin) *with* cefotaxime *or*	150–200	4
			100–180	4–6
		Vancomycin *with* cefotaxime	40–60	4
			100–180	4–6

Considering the epidemiology of L.D.'s infection and the blood culture results, she should be treated for *S. aureus* osteomyelitis. Because in both children and adults, the number of acute osteomyelitis cases caused by MRSA continues to increase, empiric IV vancomycin should be administered pending susceptibility results.[4,8] Alternative empiric therapy for L.D. with MRSA coverage includes daptomycin or linezolid.[9] Owing to limited clinical experience, these two agents should be reserved for vancomycin-intolerant cases. Clindamycin is not an option for L.D. but may be used empirically for stable patients without bacteremia or intravascular infection.[9]

The importance of antibiotic bone concentration when treating osteomyelitis is unclear, and bone concentrations do not always predict the outcome of therapy.[2,11] Theoretically, protein binding could influence clinical efficacy because only free drug is thought to diffuse from plasma into bone tissue and protein-bound drug does not. However, cefazolin (for sensitive gram-positive cocci) and

ceftriaxone (for sensitive gram-negative rods and streptococci), both highly protein-bound drugs, are well-established treatments for osteomyelitis when appropriate doses and duration are used. Therefore, antibiotic bone concentrations and protein binding of antibiotics (in appropriate doses) are not significant factors in the selection of appropriate therapy for osteomyelitis.[2,11]

Directed antibiotic therapy

CASE 73-1, QUESTION 4: The *S. aureus* grown from L.D.'s blood culture is methicillin sensitive. Considering these results, what is the optimal antibiotic regimen? Would other antibiotics given less frequently also be adequate?

L.D. is not allergic to penicillin. Although vancomycin is active against MSSA, it is inferior to β-lactams and likely to be associated with treatment failure; thus, β-lactam–based therapy should be used for susceptible organisms.[1,6] De-escalating from vancomycin to oxacillin (or nafcillin) at 150 mg/kg/day every 6 hours is appropriate.[2] Nafcillin and oxacillin are therapeutically equivalent and are given in similar doses; therefore, selection typically depends on hospital formulary considerations. Her prior exposure to amoxicillin is irrelevant except to establish the absence of a penicillin allergy.

Continuing to treat L.D. with IV oxacillin (or nafcillin) every 6 hours follows treatment recommendations for MSSA osteomyelitis. Antistaphylococcal penicillins are effective therapy with appropriate doses and duration. Changing L.D. to cefazolin would allow slightly less frequent dosing (every 8 hours), a potential advantage for home treatment. In the absence of susceptibility results or of methicillin resistance, IV vancomycin would be required for the duration of therapy. Although the logistics of outpatient parenteral antibiotic therapy (OPAT) in L.D. are being investigated, she should remain on oxacillin while in the hospital.

Duration of therapy

Case 73-1, Question 5: Both of L.D.'s parents are employed, and their work schedules prevent them from leaving their jobs to transport her to an outpatient antibiotic treatment center. Is L.D. a candidate for OPAT at home, or is oral antibiotic treatment an option? Must L.D. remain in the hospital to receive her oxacillin?

Initially, all patients should receive IV antibiotics because early, aggressive therapy offers the best chance to cure the infection. L.D., however, does not necessarily need to stay in the hospital for the duration of therapy. A peripherally inserted central catheter (PICC) can be placed, and antibiotics can be administered in an outpatient setting. The decision to use OPAT must be decided in concert with L.D.'s parents. If L.D.'s parents do not have the resources or are unwilling to oversee home therapy, L.D. should remain hospitalized for a minimum of 1 week to assess the efficacy of IV treatment. De-escalation to oral antibiotic therapy should be considered at discharge because of the frequency of PICC line complications and the cost and inconvenience of several weeks of IV therapy at home.[7,12]

As discussed in Case 73-1, Question 6, L.D. can complete most of her treatment with oral antibiotics, but oral therapy should not be given until the effectiveness of IV therapy can be assessed. Children with uncomplicated acute osteomyelitis are candidates for oral therapy when clinically improved, and the CRP has normalized, typically between 3 and 7 days.[5,8] Total duration of antibiotic therapy should be 3 to 4 weeks; however, the Infectious Diseases Society of America (IDSA) guidelines recommend 4 to 6 weeks of therapy for children with MRSA osteomyelitis.[9] Adults may receive a longer duration of IV therapy because of the chronic nature of osteomyelitis.[5] Neonatal cases warrant 4 weeks of IV antibiotics.[13]

Oral antibiotics

Case 73-1, Question 6: After 1 week of IV nafcillin, L.D. is afebrile and reports that the pain and tenderness in her left leg are much improved. Her ESR is 40 mm/hour, and CRP is 6 mg/dL. The plan is to switch L.D. to oral antibiotics

to complete a 4-week course of therapy at home. What would be an appropriate oral antibiotic regimen for L.D.? How often should she return to the clinic for evaluation?

As mentioned, oral antibiotics are only appropriate if a clear clinical response has occurred within the first week of IV therapy, the patient's parents are aware of the vital importance of medication adherence, and the patient can swallow and tolerate oral therapy.

Assuming her parents agree to supervise treatment outside of the hospital, L.D. is a candidate for oral therapy. She has responded promptly to the IV therapy: her symptoms have improved, and the ESR and CRP are trending downward. Oral therapy will be effective only if L.D. consistently takes her medications; therefore, assurances must be in place to facilitate adherence. L.D.'s parents have made arrangements with her teacher to help her take her oral antibiotic during the day.

L.D. can complete her 4-week course of antibiotics with oral cephalexin capsules or suspension, which is more palatable (and usually better tolerated) than is dicloxacillin suspension. Cephalexin should begin at 150 mg/kg/day, divided into four doses. Weekly follow-up is necessary to monitor L.D.'s adherence and clinical response to therapy. If this is not optimal, symptoms recur, or ESR or CRP increases, parenteral therapy should be reinitiated, and reevaluation is warranted.[4] Oral antibiotic doses for children with osteomyelitis are summarized in **Table 73-3**.[4,5,8,9]

Table 73-3
Oral Antibiotic Doses for the Treatment of Osteomyelitis in Children

Drug	Dose (mg/kg/day)	Doses/day
Penicillin V	125	6
Dicloxacillin	100	4
Amoxicillin	100	4
Cephalexin	150	4
Clindamycin	40	3

Linezolid		
≤12 years	30	3
>12 years	600 mg dose	2

Osteomyelitis Associated With a Contiguous Source of Infection

CLINICAL PRESENTATION

CASE 73-2

QUESTION 1: M.K., a 30-year-old male, suffered an open left femur fracture 3 weeks ago in a motorcycle accident. His fracture was stabilized by open reduction and internal fixation. His postoperative course was unremarkable until yesterday when he experienced left leg pain and spontaneous drainage from the surgical wound. On presentation, his left thigh is tender and warm, but he is afebrile. Laboratory data, including WBC count, serum creatinine, and blood urea nitrogen (BUN), are normal, but the ESR is 38 mm/hour and CRP is 8 mg/dL. Plain bone films and bone MRI show inflammation and no healing of the femur fracture.

What findings in M.K. are characteristic of secondary osteomyelitis? What organisms are most likely causing infection in M.K.?

Few of the systemic signs and symptoms associated with acute osteomyelitis are seen in contiguous-spread osteomyelitis. Some findings in acute contiguous osteomyelitis include pain in the area of infection and drainage. Considering several weeks to months might pass before the patient becomes symptomatic, radiographic study findings at the time of diagnosis might reveal abnormalities consistent with bone deterioration.[1] M.K.'s case is consistent with contiguous-spread osteomyelitis. Infection likely is at the site of surgical repair of the left femur fracture. M.K.'s localized symptoms, along with the absence of fever and leukocytosis, are characteristic of osteomyelitis after a contaminated fracture. In these cases, bone becomes infected from an exogenous source or through the spread of an infection from adjacent tissue to bone. Infection can result from

any trauma with or without subsequent orthopedic procedure to fix a bone fracture. The lower extremity bones are most commonly involved.[1] Acute contiguous infection occurs more often in adults than in children. This finding is explained by the higher incidence of precipitating factors within this age group, such as trauma, hip fractures, and orthopedic procedures.[1] Other conditions potentially associated with contiguous-spread osteomyelitis include gunshot wounds, punctures, or soft tissue infections.

Polymicrobial infection is common in contiguous-spread osteomyelitis. Although *S. aureus* is the most common pathogen, it is often part of a mixed infection. Other common pathogens include *Pseudomonas*, *Proteus*, *Streptococcus*, and *Klebsiella* species, *E. coli*, and *S. epidermidis*. Anaerobes also are associated with contiguous-spread osteomyelitis, and most commonly isolated are *Bacteroides* species and anaerobic cocci. Adjacent soft tissue infections can also lead to anaerobic bone infections, as in the case of sacral osteomyelitis secondary to severe decubitus ulcers. To identify the true pathogen(s), M.K. should have a surgical reevaluation and a biopsy of the involved bone at the probable site of infection.[1] Bone films and MRI scan will help localize the possible infectious process to direct the surgical biopsy.

Initial treatment

Case 73-2, Question 2: M.K. returns to the operating room for surgical exploration, and bone tissue is obtained for culture. He has no drug allergies, weighs 187.39 pounds (85 kg), and is 72 inches (182.88 cm) tall. The initial postoperative antibiotic order is for vancomycin, 1 g IV every 12 hours. Is this adequate antibiotic treatment for M.K.?

M.K. has had surgery to obtain bone material for culture because cultures of adjacent wound or sinus tract material are not always predictive of the bacteria actually infecting the bone.[1] Broad empiric antibiotic coverage is necessary because *S. aureus* and gram-negative aerobic bacilli most likely are causing this infection.[1]

M.K. was started on vancomycin for possible MRSA infection while awaiting results of bone tissue cultures. Given his normal renal function and weight, M.K. will likely require at least 1.25 g IV every 12 hours of vancomycin (15 mg/kg/dose) with goal area under the concentration–time curve to the minimum inhibitory concentration (AUC/MIC) ratio of 400 to 600 mg × hour/L.[14] Newer agents such as ceftaroline, dalbavancin, oritavancin, delafloxacin, and omadacycline cover MRSA and have been approved for skin infections but require further study in osteomyelitis.

To cover possible pathogenic gram-negative aerobic bacilli, a third- or fourth-generation cephalosporin (ceftriaxone, ceftazidime, or cefepime) or a quinolone (ciprofloxacin, levofloxacin) could be added. The choice of agent should, in part, be based on local susceptibility patterns. Some experts recommend avoiding quinolones, if possible, in osteomyelitis associated with fractures, citing potential concerns with bone healing.[1]

Anaerobic coverage should be initiated if an anaerobe is cultured from bone or anaerobes are suspected. Vancomycin has activity against gram-positive anaerobes, but not against the gram-negative anaerobe, *Bacteroides fragilis.* If *B. fragilis* is cultured from bone, additional therapy with metronidazole is indicated. Alternatively, a β-lactam/β-lactamase inhibitor combination therapy with piperacillin/tazobactam, or a carbapenem could provide broad-spectrum aerobic (including *Pseudomonas)* and anaerobic gram-negative coverage.

While cultures are pending, M.K. is receiving vancomycin 1.25 g IV every 12 hours and cefepime 2 g IV every 8 hours.

DIRECTED THERAPY

Case 73-2, Question 3: The bone biopsy from M.K. grows MRSA that is sensitive to vancomycin, linezolid, and trimethoprim/sulfamethoxazole. His leg pain is no worse than it was 2 days ago, and he remains afebrile. How should M.K. now be treated? Is he a candidate for oral therapy?

Because no gram-negative organisms grew on culture, cefepime should be discontinued. Therapy should be directed against MRSA. Thus, it is justified to continue treating M.K. with vancomycin as long as he is monitored closely, following up on his symptoms, periodic vancomycin serum concentrations that permit AUC-guided dosing and monitoring, weekly ESR or CRP concentrations, CBC, and metabolic panel.[14] Vancomycin can be administered as OPAT. Alternatively, studies have shown that oral antibiotics can achieve adequate concentrations in bone and that they may be noninferior to parenteral agents, permitting partial oral antibiotic therapy in selected patients with osteomyelitis.[15] Based on clinical improvement and provider preference, M.K. may be transitioned to oral linezolid (600 mg twice daily) for 6 total weeks of therapy.[1] He should be followed up closely for at least 2 years to detect recurrent infection.

Osteomyelitis Associated With Vascular Insufficiency

CLINICAL PRESENTATION

CASE 73-3

Question 1: M.S., a 55-year-old female, presents to the diabetes clinic with an ulcer 2 cm wide × 1 cm deep on the left lateral aspect of her foot that she first noted a month ago. Her primary care physician had prescribed a 2-week course of ciprofloxacin and gave her instructions for regular wound care. A few days before her clinic visit, the callus surrounding the ulcer cracked open and a small piece of bone protruded from the wound. She reports mild swelling and redness but denies any pain, fever, or chills. Her past medical history includes type 2 diabetes mellitus, hypertension, peripheral neuropathy, and chronic kidney disease requiring hemodialysis three times a week. Laboratory findings include WBC 5200/μL with normal differential, BUN 56 mg/dL, serum creatinine 5.6 mg/dL, fasting blood glucose 240 mg/dL, hemoglobin $A1_c$ (HbA_{1c}) 12.4%, and ESR 45 mm/hour.

What findings in M.S. are consistent with osteomyelitis secondary to vascular insufficiency?

M.S. has chronic lower extremity vascular insufficiency because of type 2 diabetes. Patients with impaired blood flow may develop osteomyelitis in the toes or small bones of the feet. Infection often first presents as cellulitis, as in M.S.'s case, progressing to deep ulcers and, finally, to the underlying bone.

Similar to contiguous-spread osteomyelitis, systemic signs of infection (eg, fever and leukocytosis) are often absent in patients who experience bone infection secondary to vascular insufficiency. Local symptoms such as pain, swelling, and erythema usually predominate, but there are no specific clinical findings.[15]

M.S. may have a bone infection under the chronic, cutaneous ulcer on the bottom of her left great toe. Because of peripheral neuropathy, the skin lesion may not be painful, and poor blood supply to the site likely contributed to the development of a chronic infection and possibly secondary osteomyelitis. The true depth of an ulcer is not always clinically apparent, so careful physical examination and evaluation of patient risk factors are essential for diagnosis.[16] Infection is suggested by her elevated ESR, fasting glucose (consistent with infection), and HbA_{1c} (indicating uncontrolled diabetes). In addition, diabetic foot ulcers with an area >2 cm^2 or that penetrate to bone are often predictive of underlying osteomyelitis.[16]

ANTIBIOTIC SELECTION

Case 73-3, Question 2: M.S. is admitted into the hospital for diagnosis, wound care, and antibiotics. Plain films show destruction of the distal left fifth metatarsal with bony changes consistent with osteomyelitis. Her wound is debrided, and material obtained from a bone biopsy is sent to the microbiology laboratory for cultures. She has no drug allergies and is started on vancomycin (1 g IV every 12 hours) and oral ciprofloxacin (750 mg every 12 hours). Is this appropriate initial, empiric therapy?

In many cases of osteomyelitis associated with vascular insufficiency, multiple pathogens will be cultured from surgical specimens or the wound. The most commonly isolated pathogen is

S. aureus; however, gram-negative and anaerobic bacteria are also often recovered. The bacteria isolated from a wound or soft tissue culture may not correlate with bacteria found in a concomitant bone biopsy, so bone biopsy is preferred when possible.[16],[17] Empiric antibiotic therapy for osteomyelitis associated with vascular insufficiency should be active against both gram-positive and gram-negative aerobic bacteria and possibly anaerobes. No specific regimens have demonstrated superiority, so a broad-spectrum empiric regimen can be chosen based on local sensitivity patterns.[1] Frequently used empiric regimens for gram-negative and anaerobic coverage are an antipseudomonal β-lactam (piperacillin-tazobactam, cefepime) or quinolone (ciprofloxacin, levofloxacin) with metronidazole.

M.S. has risk factors for MRSA and resistant gram-negative bacilli because of her diabetes, hemodialysis, and recent course of antibiotics. The initial regimen of vancomycin and ciprofloxacin for M.S. is not optimal for several reasons. Because of her recent, prolonged ciprofloxacin exposure, a quinolone-resistant organism may be responsible for infection and a β-lactam–based antibiotic regimen would be more appropriate. Secondly, IV antibiotics should be used during initial treatment. Lastly, M.S. is dialysis dependent, and the antibiotic regimen selected should be dose adjusted according to her renal function. Vancomycin should be intermittently dosed based on her dialysis regimen and maintaining predialysis serum drug concentrations to achieve the desired AUC.[14] The dose for M.S.'s cefepime is 1 g IV every 24 hours, with the dose administered after dialysis on dialysis days.

Antibiotic de-escalation should occur after the results of the deep wound swab culture are available. The optimal duration of IV therapy for diabetic foot osteomyelitis is patient dependent. Some patients may require longer-term, oral suppressive therapy depending on the degree of surgical debridement and the healing rate of the ulcer.[16] The overall duration varies and generally should not exceed 6 weeks.[1],[16] Oral linezolid (600 mg every 12 hours) has been used to treat MRSA osteomyelitis in patients with diabetes, although long-term therapy can be associated with hematologic and neuropathic

adverse effects.[18] Osteomyelitis associated with diabetic foot ulcers is difficult to treat. Despite adequate surgical debridement of the infection followed by appropriate treatment with long-term IV and oral antibiotic therapy, cure rates are low.

Chronic Osteomyelitis

CLINICAL PRESENTATION

CASE 73-4

Question 1: J.F., a 52-year-old male, sustained a fracture of the right humerus in a farming accident 6 years ago. That fracture clinically healed without any immediate consequences; however, 1 year ago, a draining sinus tract developed at the site of the previous fracture without any antecedent events. Two weeks ago, he noted increased sinus drainage, pain, swelling, and erythema of his left upper arm, and levofloxacin was restarted. A swab culture of the sinus drainage grew *S. epidermidis*, *E. coli*, *Peptostreptococcus micros*, and *Bacteroides* species. Surgical debridement of bone and tissue was performed because of increased drainage and poor appearance of the wound. Gentamicin-impregnated polymethylmethacrylate (PMMA) beads were placed in the tissue adjacent to the debrided bone during surgery. Bone cultures grew *Proteus mirabilis* and *B. fragilis.* The *Proteus* was resistant to ampicillin, cefazolin, levofloxacin, and tigecycline but sensitive to cefotaxime, ceftriaxone, imipenem, gentamicin, and trimethoprim-sulfamethoxazole. Antibiotic susceptibilities for the *Bacteroides* were not tested.

What aspects of J.F.'s case are characteristic of chronic osteomyelitis?

Despite appropriate initial therapy, osteomyelitis can reactivate, even with organisms different from the initial episode. Some propose that previously infected bone might be a risk for reinfection. Persistent symptoms or signs lasting >10 days are consistent with chronic osteomyelitis and the development of necrotic bone. Draining sinus tracts often develop from the bone to the skin with chronic osteomyelitis.[19] J.F. probably experienced a chronic bone infection after the farming accident. The reappearance of sinus tract drainage in his left upper arm indicates an indolent infection of the bone that was periodically suppressed, but not completely treated by

oral antibiotics. Cultures of sinus drainage now reveal multiple organisms including normal skin flora. These sinus tract cultures usually do not correlate with the organisms actually causing bone infection. J.F.'s recurrent course of bone involvement with drainage and local symptoms, and lack of any remarkable systemic symptoms, suggest chronic osteomyelitis.[19]

SURGERY AND ORAL ANTIBIOTICS

Case 73-4, Question 2: Oral levofloxacin was started 2 weeks ago when J.F.'s left arm became more painful, and drainage increased. Was his poor response to therapy unexpected? How should his case have been managed?

J.F.'s poor response should have been expected for at least two reasons: Antibiotic therapy was started before surgical debridement of avascular tissue, and he was given an antibiotic that was inactive against the cultured bone organisms.

Surgery plays an important role in the treatment of chronic osteomyelitis. Bone necrosis will continue to progress if decompression and drainage of the infected area are not carried out as soon as possible. Furthermore, without dead space management including initial surgical removal of necrotic bone (sequestrum) and other poorly vascularized, infected material, even the most optimal IV antibiotics are likely to fail.[20]

After surgery, antibiotic therapy directed against the pathogens isolated in the surgical specimens should be started. The regimen choice should not be based on the sinus tract culture results because these isolates may not correlate with the actual causative organisms. J.F. should be treated initially with IV antibiotics because of relatively poor blood flow at the infection site. Although the optimal duration of antibiotic therapy for chronic osteomyelitis is not well established, the standard recommendation has been 6 weeks. The susceptibility of the organism to the antibiotic is more relevant than is the route of administration.[15],[21],[22] J.F. should continuously be

evaluated by an orthopedic surgeon because he may require further surgical treatment to eradicate chronically infected bone.

INTRAVENOUS ANTIBIOTICS

Case 73-4, Question 3: What would be reasonable antibiotic therapy for J.F.?

Based on the bone culture and sensitivity results, J.F. needs high-dose therapy directed at *P. mirabilis* and *B. fragilis.* For convenience and possible future home therapy, ceftriaxone (2 g IV every 24 hours) could be started for coverage of *Proteus* with metronidazole (500 mg IV every 8 hours) for coverage of *B. fragilis*. Because of excellent oral bioavailability, metronidazole can be rapidly converted to oral therapy at the same dose before discharge. Ertapenem is an alternative choice for home IV therapy assuming that the *Proteus* isolate is sensitive. This agent also provides excellent anaerobic activity, and its once-daily dosing (1 g IV every 24 hours) is convenient for OPAT. J.F. should be evaluated for response. If symptoms have abated, treatment with oral antibiotics (trimethoprim-sulfamethoxazole and metronidazole) may commence and should continue for a total of ≥6 weeks depending on resolution of the sinus tract drainage, pain, and tenderness in J.F.'s arm. Under these circumstances, he should be monitored closely for possible long-term adverse drug effects (eg, hepatitis, cytopenias, neuropathy). If the sinus tract does not heal or if J.F. remains symptomatic, surgical exploration and bone cultures must be repeated.

LOCAL ANTIBIOTICS

Case 73-4, Question 4: What is the rationale for and effectiveness of local antibiotic administration (the PMMA beads) inserted during J.F.'s orthopedic surgery?

To deliver high concentrations of antibiotics to poorly vascularized bone infection sites, various materials containing antibiotics can be

placed at the infection site during surgery. Plaster pellets, fibrin, collagen, hydroxyapatite, and PMMA impregnated with antibiotic, usually an aminoglycoside or vancomycin, are used. The dosage form is designed for the slow release of antibiotics from the material. The most commonly reported experience with local antibiotic delivery has been with antibiotic-impregnated PMMA cement or beads inserted during joint arthroplasty. Local delivery of antibiotics should not replace systemic antibiotics in the treatment of chronic osteomyelitis.[20]

Orthopedic Implant–Associated Infections

USUAL CLINICAL PRESENTATION

CASE 73-5

Question 1: A.T., a 47-year-old female, had a left knee replacement 1 year ago for osteoarthritis. She presents today to the orthopedic clinic because of increasing left knee pain for the past 2 months. The knee is painful and warm. She is afebrile, and her peripheral WBC count is 9800/μL. Aspiration of fluid from the knee reveals a total nucleated cell count of 78,000/μL with 90% neutrophils. A Gram stain of this fluid shows 4+ polymorphonuclear leukocytes (PMNs) and 1+ gram-positive cocci. She is started on antibiotic therapy with vancomycin and ciprofloxacin pending culture results, and she is scheduled for operative evaluation and possible removal of her prosthetic joint.

Does A.T. have a periprosthetic joint infection?

Joint replacement surgery is commonly performed in patients with significant joint destruction as a result of arthritis and other disabling diseases. Prosthetic knee, shoulder, elbow, or hip devices made of metallic alloys are cemented to the adjacent bone to reestablish joint function. Infection of these foreign bodies can occur because of exogenous inoculation of bacteria perioperatively, via hematogenous dissemination of bacteria, or by contiguous spread from a topical wound. Bacterial infection of bone adjacent to the joint prosthesis, including the bone–cement interface, may result in a loosened and less functional prosthesis.[23] *Staphylococcus* species including

coagulase-negative species such as *S. epidermidis* are most commonly involved in prosthetic joint infections, followed by *Streptococcus* species, gram-negative bacilli, and anaerobes. Although coagulase-negative staphylococci are usually considered a contaminant in culture, this organism readily adheres to prosthetic material and should be considered pathogenic when cultured from prostheses. Coagulase-negative staphylococci are often methicillin resistant but susceptible to vancomycin.

Chronic pain, swelling, erythema, and tenderness over a prosthetic joint are typical findings associated with prosthetic joint infection. Persistent wound drainage may also be present. A.T. has had a relatively lengthy duration of symptoms associated with her left knee, which could be caused by joint loosening, but the cell count and differential from the joint aspirate suggest joint infection. Consistent with infected prosthesis is also the predominance of neutrophils in her joint fluid and gram-positive cocci on a Gram stain finding. As is often the case, she has no obvious preceding source of infection from which bacteria may have originated. Occasionally, sources of infection with hematogenous dissemination to the prosthetic joint are identified, such as dental infections, cellulitis, or urinary tract infections. Given the Gram stain result, A.T. should receive coverage for *Staphylococcus* and *Streptococcus* species with vancomycin while awaiting the results of cultures and sensitivities. Because gram-negative bacteria also can infect these joints, gram-negative coverage is reasonable until the results of joint fluid cultures are available.

SURGERY

CASE 73-5, QUESTION 2: Does A.T. need surgery and antibiotics to cure her infection?

Surgical removal of A.T.'s knee prosthesis in conjunction with systemic antibiotics for 6 weeks is the current recommendation for optimal eradication of prosthetic joint infection.[23],[24] A two-stage

orthopedic procedure that involves removal of the infected prosthesis, placement of an antibiotic-filled spacer, joint immobilization, and antibiotics for 6 weeks is frequently used. If the joint space culture result remains negative after 2 weeks of antibiotics, a new joint prosthesis is then reinserted. Because avascular bone cement and prosthetic material can become seeded with bacteria, complete removal of this material is necessary to have the greatest chance of curing the infection. Six weeks of systemic antibiotic therapy in combination with orthopedic surgery results in restoration of joint function in >80% of cases. High rates of treatment failure occur if the joint prosthesis is not removed, the antibiotic duration is too short, and if chronic suppressive antibiotics are not given.[23],[24]

ANTIBIOTICS

CASE 73-5, QUESTION 3: The surgeon is unable to completely remove A.T.'s prosthetic joint. The removed lining material and three swabs of the left knee prosthesis grow MRSA. What antibiotic regimen could be used? How long should A.T. be treated?

Because A.T.'s prosthesis cannot be removed, she will need 2 to 6 weeks of vancomycin (15 mg/kg IV every 12 hours) plus oral rifampin (450 mg orally [PO] bid), followed by 6 months of oral antibiotics plus rifampin.[24] Daptomycin (6–10 mg/kg IV daily) or linezolid (600 mg PO/IV every 12 hours) are alternatives to vancomycin, depending on pathogen susceptibility, drug allergies or intolerances, and potential drug–drug interactions.[24],[25] However, these agents are not U. S. Food and Drug Administration (FDA) approved for prosthetic joint infections, and they require monitoring for adverse effects, such as creatine kinase elevations (daptomycin) and bone marrow suppression and neuropathy (linezolid).[23] Combination therapy with rifampin should be used for prosthetic joint infection caused by staphylococci, particularly if removal of the infected prosthesis is not possible, because rifampin penetrates bacterial membranes and biofilms to enhance the bactericidal activity

of the antibiotic regimen. Monotherapy with rifampin should never be used because of the rapid development of resistance.[26,27] Rifampin induces the metabolism of multiple other agents (eg, warfarin, anticonvulsants, azole antifungals); therefore, a thorough review of A.T.'s medication profile is critical. A.T.'s baseline liver function should also be evaluated and rechecked at least monthly while she is taking rifampin.[28] In addition, weekly assessment of A.T.'s CBC and renal function along with periodic vancomycin serum concentrations that permit AUC-guided dosing and monitoring should be performed.[14]

SEPTIC ARTHRITIS

Septic arthritis or infectious arthritis is usually acquired hematogenously. The highly vascular synovium of the joint allows easy passage of bacteria from blood into the synovial space. Bacteremia, secondary to *Neisseria gonorrhoeae* or *S. aureus* in particular, often is associated with joint infections. Septic arthritis also can develop secondary to inoculation of pathogens because of trauma, including puncture (eg, animal bites, nail) or surgery, as well as via contiguous spread from osteomyelitis.[29]

Several factors predispose patients to the development of infectious arthritis. Patients with abnormal joint structure, including rheumatoid arthritis (RA), prosthetic joints, or recent joint surgery, are more susceptible to the development of infection. Patients 80 years or older and having diabetes mellitus and chronic illnesses such as malignancy and chronic renal failure are also at an increased risk. Gonococcal arthritis may occur in those who have been exposed to or are infected with *N. gonorrhoeae*.[29,30]

Clinical Presentation of Nongonococcal Arthritis

CASE 73-6

Question 1: C.H., a 45-year-old male, is referred to the rheumatology clinic for left knee swelling. Two days ago, his left knee became painful and swollen, and he is unable to flex the joint. He also recorded temperatures at home of 100.7 °F (38.17 °C) to 102 °F (38.89 °C) for at least 4 days. In clinic, a joint effusion is noted, and fluid is aspirated for cell count, Gram stain, and culture. His medical history is unremarkable. C.H.'s WBC count is 16,000/μL, and his ESR is 42 mm/hour. The synovial fluid from his right knee contains 30,000 WBC/μL with 90% neutrophils, and the Gram stain finding shows gram-positive cocci in clusters. Culture and sensitivity results are pending. His current temperature is 101.3 °F (38.5 °C).

What findings in C.H. are consistent with septic arthritis?

C.H. has an acute onset of monoarticular joint pain and swelling, with a reduced range of motion and fever. These findings are classic for septic, nongonococcal arthritis. The joint effusion shows a predominance of neutrophils, which confirms the diagnosis. C.H.'s knee has been infected hematogenously from a distant, unrecognized, source of infection, and the most common causative pathogens are gram positive, including *Staphylococcus* and *Streptococcus* species.

A single joint, most frequently the knee, is infected in 80% to 90% of nongonococcal arthritis cases. Other possible sites of infectious arthritis in adults include the hip, shoulder, elbow, ankle, and wrist joints.[29,30] Patients commonly present with fever, pain, swelling, redness, and decreased mobility of the involved joint.

As illustrated by C.H., most patients have joint effusion on physical examination. When evaluating a patient with possible septic arthritis, any purulent joint effusion should be considered septic until proven otherwise. Alternatively, noninfectious conditions may be present, such as acute RA, gout, or chondrocalcinosis.[29]

Aspirated joint fluid should be cultured because isolation of bacteria is the only definitive diagnostic test for bacterial arthritis. C.H.'s joint fluid picture is typical. The leukocyte count in the synovial fluid usually is elevated significantly, often with counts >50,000/μL with a predominance of neutrophils (>75%). Blood culture results are positive in 25% to 70% of patients, and 80% to 90% of patients will have positive synovial fluid culture results.

Another laboratory finding in C.H. consistent with infectious arthritis is the elevated ESR and peripheral WBC count. CRP is frequently elevated as well, although both ESR and CRP are nonspecific markers of inflammation and can be elevated owing to causes other than infectious arthritis.

The patient's age impacts the most common bacterial cause of infection. In adults older than age 30 years, such as C.H., and in children older than age 2 years, *S. aureus* is the most common bacterial source. In sexually active young adults, *N. gonorrhoeae* is more likely to be the causative agent. Streptococci, such as group A β-hemolytic streptococci, can cause infection in children and adults. Group B streptococci, anaerobic streptococci, and gram-negative bacteria can also cause infection. Gram-negative bacilli are responsible for ~5% to 20% of cases and often infect multiple joints. Infections with gram-negative bacteria usually are associated with predisposing factors, such as RA, osteoarthritis, history of joint surgery, intra-articular injections, or IV drug use. An organism commonly isolated from patients with bacterial arthritis and a history of IV drug use is *P. aeruginosa*.[29,30]

Initial Antimicrobial Therapy

Case 73-6, Question 2: How should C.H. be treated, and for how long? How should the treatment efficacy be monitored?

Treatment of nongonococcal arthritis includes drainage of purulent joint fluid (by needle aspiration or surgery) and appropriate antibiotic therapy guided by patient presentation and synovial fluid Gram stain. Because of the increasing frequency of health care–associated and community-acquired MRSA causing infection, initial empiric therapy with vancomycin (15–20 mg/kg/dose IV every 12 hours in normal renal function, goal AUC/MIC ratio of 400–600 mg-h/L) should be initiated to provide coverage for this and streptococci in C.H.[14] Daptomycin and linezolid are typically reserved for patients with vancomycin intermediate-susceptible or resistant gram-positive

organisms, or those patients with intolerance, allergy, or nonresponse to vancomycin. More data assessing use in septic arthritis are needed before other antibiotics with MRSA coverage can be recommended, such as dalbavancin, oritavancin, ceftaroline, delafloxacin, or omadacycline. Vancomycin can be changed on the basis of sensitivity testing to oxacillin, nafcillin, or cefazolin if the isolated organism is susceptible.[29],[30]

DURATION OF THERAPY

Optimal duration of therapy for bacterial arthritis remains unknown.[29] Previous recommendations based on early clinical trials recommended treating for 2 to 3 weeks.[31] Current recommendations are to treat with 2 to 4 weeks of antibiotics, initially parenteral, followed by oral antibiotics (if possible, based on susceptibilities and drug bioavailability).[29],[32] Injections of antibiotics into the joint space are of no value. Most systemic antibiotics readily penetrate the joint space and enter the synovial fluid.

C.H. should be treated for at least 4 weeks if his infection is caused by *S. aureus*.[29] His response to therapy should be monitored clinically (resolution of symptoms, fever, and falling ESR, CRP, or both) as well as by periodic evaluation of joint fluid. Frequent aspirations of joint fluid via closed-needle aspiration or following arthroscopic lavage, and debridement and insertion of drains are needed in more severe cases and will permit daily evaluation of cell count and fluid culture. Effective therapy should result in a decreasing WBC count in the joint fluid and negative culture findings.[29]

Joint inflammation and other symptoms also should diminish during the first week of treatment. The duration of articular symptoms before antibiotic therapy begins correlates with the subsequent time required to sterilize the synovial fluid. Therefore, delay in initiating antibiotic treatment may necessitate a longer course of therapy.

Gonococcal Arthritis

Polyarticular arthritis in a young, sexually active adult is frequently caused by *N. gonorrhoeae.* Arthritis in multiple joints is a common feature of disseminated gonococcal infection (DGI). Unlike nongonococcal arthritis, which is almost exclusively monoarticular, gonococcal arthritis involves multiple joints in 42% to 85% of cases. Females have a fourfold increased risk of developing gonococcal arthritis as compared with males, often due to delays in diagnosis of genital infection.[29,33] Clinically, patients present with a migratory polyarthralgia and often with fever, dermatitis, and tenosynovitis. Skin lesions are an important clue to the diagnosis of DGI and often begin as tiny erythematous papules that develop into larger vesicles. As in hematogenously acquired nongonococcal arthritis, the synovial fluid leukocyte count usually is elevated, but often to a lesser degree. *N. gonorrhoeae* is recovered in ~50% of purulent joint effusions and is detected using polymerase chain reaction (PCR) assays with ~80% sensitivity. These laboratory studies, coupled with the patient's clinical presentation, can be used to make a definitive diagnosis.[29,33]

CLINICAL PRESENTATION OF GONOCOCCAL ARTHRITIS

CASE 73-7

Question 1: E.D., a 21-year-old female, presents to the walk-in clinic with right knee and right shoulder pain, nausea, and vomiting. On physical examination, her right knee is swollen, and she has decreased range of motion of her right shoulder. Several erythematous, papular skin lesions are noted on both hands. She also has a vaginal discharge. Her temperature is 100.76 °F (38.2 °C), and her WBC count is 15,000/μL. She gives a history of having two recent sexual partners. Culture results of blood, joint fluid, and vaginal discharge are obtained; a joint fluid Gram stain shows 4+ PMNs, but no organisms are seen.

Why is E.D. considered to have gonococcal arthritis?

E.D. has systemic signs of infection (fever, nausea, vomiting, leukocytosis), skin lesions, and multiple joint involvement, which are classic for DGI. Her history of recent sexual activity and the presence of a vaginal discharge are consistent with gonococcal

infection, although evidence of mucosal infection with *N. gonorrhoeae* is not necessary for disseminated infection to occur.[29],[33]

PATIENT WORKUP AND TREATMENT IN THE CLINIC

Case 73-7, Question 2: What additional workup should be done in E.D.? Can she be treated immediately in the clinic?

A nucleic acid amplification test (NAAT) should be performed using a specimen obtained from E.D.'s cervix. E.D. should also be evaluated for other sexually transmitted infections, specifically syphilis and HIV infection. Serologic testing for syphilis (rapid plasma reagent [RPR] or venereal disease research laboratory [VDRL] testing) and for antibody to HIV should be obtained. In addition, she should have a pregnancy test because some of the antibiotics that may be used are contraindicated during pregnancy, including doxycycline.

Because of possible penicillinase production and widespread fluoroquinolone resistance with *N. gonorrhoeae*, recommended therapy is with ceftriaxone (1 g intramuscularly or IV every 24 hours). E.D. should receive her first dose of ceftriaxone in the clinic today. Conversion to oral antibiotics should be guided by antimicrobial susceptibility testing following 24 to 48 hours of clinical improvement by the patient.[34]

E.D.'s sexual partners should also be evaluated and treated for relevant sexually transmitted infections. She should also be counseled on utilization of barrier methods (eg, condoms) to prevent sexually transmitted infections.

FULL COURSE OF THERAPY

Case 73-7, Question 3: Results of RPR and pregnancy testing in E.D. are negative. How should she complete her course of therapy?

E.D.'s DGI should be treated for at least 7 days. E.D. also should begin treatment with azithromycin (1 g PO once) or doxycycline (100 mg PO twice daily for 7 days) for the possibility of concomitant chlamydial infection. Azithromycin is preferred because of its increasing resistance to tetracyclines.[35] Treatment guidelines for DGI are also included in the section on Gonorrhea in Chapter 72, Sexually Transmitted Diseases.

Skin and Soft Tissue Infections

Cheryl R. Durand and Kristine C. Willett

CORE PRINCIPLES		CHAPTER CASES
SKIN AND SOFT TISSUE INFECTIONS		
1	Cellulitis (an acute inflammation of the skin and subcutaneous fat) is characterized by local tenderness, pain, swelling, warmth, and erythema with or without a definite entry point.	**Case 74-1 (Question 1, 5)**
2	Cellulitis is most often caused by group A β-hemolytic streptococci (*Streptococcus pyogenes*) and, less often, *Staphylococcus aureus.*	**Case 74-1 (Question 1), Table 74-1**
3	Community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) may be a causative pathogen, especially in high-risk patients (children, competitive athletes, prisoners, soldiers,	**Case 74-1 (Question 1) Case 74-3 (Question 1)**

	selected ethnic populations, Native Americans/Alaska Natives, Pacific Islanders, intravenous drug users, men who have sex with men [MSM]), and empiric treatment should have activity against CA-MRSA.	
4	For most cases of cellulitis requiring antibiotics, the least expensive of dicloxacillin or cephalexin should be chosen. Cases of cellulitis as evidenced by signs of systemic infection require parenteral antibiotics. The duration of therapy should be at least 5 days.	**Case 74-1 (Questions 1–4, 6) Case 74-2 (Question 1, 2)**
5	Conversion to oral antibiotic therapy should be considered when patients show signs of clinical improvement and are afebrile for at least 24 hours.	**Case 74-2 (Questions 3, 4)**
6	Abscesses, furuncles, and carbuncles are commonly caused by *S. aureus* and should be managed with incision and drainage. Antibiotic therapy is warranted when systemic inflammatory response syndrome is present.	**Case 74-3 (Questions 2, 3), Table 74-1**
	ERYSIPELAS	
1	Oral or parenteral penicillins, with activity against group A streptococci, are the drugs of choice for treatment.	**Case 74-4 (Question 1), Table 74-1**
	SKIN AND SOFT TISSUE INFECTIONS IN PATIENTS WITH DIABETES	
1	Skin and soft tissue infections are very common in patients with diabetes, with	**Case 74-5 (Question 1)**

	~25% of patients reporting a history of skin and soft tissue infection.	
2	Mild infections in patients with diabetes can be treated similar to cellulitis (gram-positive coverage), whereas moderate-to-severe infections require broad-spectrum coverage.	**Case 74-5 (Questions 1–4), Table 74-1**
	NECROTIZING SOFT TISSUE INFECTIONS	
1	Necrotizing soft tissue infections can progress rapidly to cause local (eg, necrosis and loss of skin sensation) and severe systemic (eg, hypotension, shock) effects.	**Case 74-6 (Question 1)**
2	Initial treatment of necrotizing soft tissue infections involves extensive debridement to remove all necrotic tissue, fluid resuscitation, and broad-spectrum antibiotics.	**Case 74-6 (Question 1), Table 74-1**
	ANIMAL BITES	
1	Animal bites (eg, from cats, dogs) necessitate irrigation of the wound to reduce the risk of infection and treatment may include coverage against aerobic or anaerobic organisms (oral flora of the animals). Amoxicillin/clavulanate is the preferred first-line agent.	**Case 74-7 (Questions 1, 2), Table 74-1**
	HUMAN BITES	
1	Treating a human bite is similar to that of any other laceration, including	**Case 74-8 (Question 1), Table 74-1**

cleansing, irrigating, exploring, debriding, draining, excising, and suturing, as required. Human-bite infections may be caused by aerobic and anaerobic organisms and should be treated with amoxicillin/clavulanate or ampicillin/sulbactam, or ertapenem.

INTRODUCTION

Skin and soft tissue infections may involve any or all layers of the skin (epidermis, dermis), subcutaneous fat, fascia, or muscle. Many terms or classifications describe various skin and soft tissue infections, and these often are based on the site of infection and causative organism(s).[1] This chapter focuses on skin and soft tissue infections that are primarily the result of a break in the skin after an abrasion, skin puncture, ulceration, surgical wound, intentional or unintentional insertion of a foreign body, or blunt soft tissue contusion. Treatment of skin and soft tissue infections often is empiric and based on the severity and site of infection, presence of purulence, the patient's underlying immunocompetence, and the triggering event (eg, abrasion, bite, insertion of a foreign object) because attempts to isolate the causative organism often are futile.

SKIN AND SOFT TISSUE INFECTIONS

Cellulitis (an acute inflammation of the skin and subcutaneous fat) is characterized by local tenderness, pain, swelling, warmth, and erythema with or without a definite entry point. Cellulitis is usually secondary to trauma or an underlying skin lesion that allows bacterial penetration into the skin and underlying tissues. Cellulitis is most often caused by group A β-hemolytic streptococci

(*Streptococcus pyogenes*) and other streptococcus species (B, C, F, or G), and less often, *Staphylococcus aureus* (**Table 74-1**).[2] However, if the patient presents with abscess, purulence, or penetrating trauma, coverage of *S. aureus* is indicated.[2] Coverage for community-acquired methicillin-resistant *Streptococcus aureus* (CA-MRSA) may be warranted because the incidence has been increasing.[3] Gram-negative organisms (eg, *Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae*) also can cause cellulitis but should be suspected only in patients who are immunocompromised or in patients who fail to respond to antibiotics with activity limited to gram-positive organisms. Wound cultures often are negative and fail to identify the causative organism.

Table 74-1

Potential Organisms Causing Skin and Soft Tissue Infections

	Gram Positive		Gram Negative		Anaerobes			
	Staphylococci	Streptococci	*Escherichia coli*, *Klebsiella* Species, *Proteus* Species	*Pasteurella multocida*	*Eikenella corrodens*	Oral Anaerobes	*Clostridium* Species	*Bacteroides fragilis*
Cellulitis	X	X

Clinical practice guidelines for the diagnosis and treatment of diabetic foot infections. *Clin Infect Dis*. 2012;54:e132–e173.

Severity of infection is based on the presence of systemic signs of infection, failure of oral antibiotics, and immunocompetence. Cases

of mild cellulitis without signs of systemic infection often require treatment with antibiotics active against streptococci. Patients with evidence of a systemic infection, suggesting a moderate-to-severe infection, will require intravenous (IV) antibiotics, in addition to local wound care. Severe infections occur in patients who have failed oral antibiotic therapy or those who are immunocompromised. Antibiotic selection is based on the suspected etiology as well as severity of infection.

In addition to cellulitis, skin and soft tissue infections include abscesses, furuncles, and carbuncles. A skin abscess is an infection and results in a collection of pus within the dermis and deep skin tissues.[2] Furuncles are abscesses that initiate in the hair follicle and penetrate into the surrounding subcutaneous tissue, whereas carbuncles are a coalescence of furuncles.

CASE 74-1

QUESTION 1: N.P., a 25-year-old female, presents to her family doctor with a 2- to 3-day history of worsening pain, redness, and swelling on her left leg following an abrasion that occurred after falling while jogging in the park. The area is red, painful, nonpurulent, and warm to the touch. During the past 24 to 36 hours, the leg has become increasingly painful and "tight." N.P. denies having fever or chills. The presumptive diagnosis is a mild cellulitis, and dicloxacillin is prescribed.

Why is dicloxacillin appropriate empiric treatment for N.P.?

Oral dicloxacillin is appropriate empiric therapy for cellulitis in an otherwise healthy individual with no signs or symptoms of systemic infection, regardless of the presence of purulence. Dicloxacillin has predictable activity against streptococci and methicillin-sensitive staphylococci and is better tolerated than is erythromycin or clindamycin. Because the patient presents with nonpurulent cellulitis, penicillin VK is also an option; however, it lacks coverage against staphylococcus. If the cellulitis is well demarcated and nonpurulent, penicillin alone can be appropriate because the causative organism is likely to be *Streptococcus*. Many other available antibiotics that have activity against staphylococci and streptococci have been

evaluated for effectiveness in skin and soft tissue infections. A recent review concluded that the available evidence does not allow specific recommendations for the best antibiotic regimen for cellulitis.[3,4] Cephalexin is probably as effective and as well tolerated as dicloxacillin and is comparable in cost. However, the gram-negative activity of cephalexin (not present with dicloxacillin) is not required for most cases of cellulitis in otherwise healthy patients. For N.P., antibiotic treatment is required, and she can receive dicloxacillin or cephalexin.

In geographic areas with higher incidence of CA-MRSA (>10% of isolates), particularly in patients with additional risk factors (children, competitive athletes, prisoners, soldiers, selected ethnic populations, Native Americans/Alaska Natives, Pacific Islanders, IV drug users, men who have sex with men [MSM]), empiric treatment should include antibiotics with activity against CA-MRSA.[5] In cases of an abscess without signs of systemic infection, drainage is often all that is needed because antibiotic therapy has not been shown to be better than is placebo for uncomplicated skin abscesses in a population at risk for CA-MRSA infection.[6] At present, most CA-MRSA are still susceptible to trimethoprim-sulfamethoxazole, clindamycin, and doxycycline.[2] Although trimethoprim-sulfamethoxazole has good activity against *S. aureus*, its activity against *S. pyogenes* (group A streptococci), is weak, rendering this antibiotic undesirable alone as empiric therapy. If these agents are used, a reasonable suggestion would be to reevaluate (by the patient if they are competent) within 24 to 48 hours to verify that an improvement is occurring. Some clinicians avoid the use of clindamycin because of concerns of inducible resistance. In areas with a clinically important incidence of CA-MRSA, laboratories should test for inducible clindamycin resistance. If N.P. is from an area of high CA-MRSA prevalence and has associated risk factors, the combination of trimethoprim-sulfamethoxazole or doxycycline with β-lactam (penicillin, cephalexin, amoxicillin) would provide therapy for the anticipated pathogens. However, even in areas of high CA-MRSA prevalence, some investigations have found cephalexin to be as effective as therapy specifically targeted for CA-

MRSA, although this has not been supported in all studies.[7–9] If CA-MRSA does not require antibacterial coverage, this practice may reduce antibacterial selection pressure and expense.[10]

Case 74-1, Question 2: What agents could be chosen if N.P. is allergic to penicillin?

Clindamycin could be selected for patients with a documented history of penicillin or cephalosporin allergy.[2] In certain geographic areas, group A streptococci macrolide resistance approaches 15% to 20%, decreasing the potential value of this agent. Clindamycin is superior to macrolides with respect to group A streptococcal coverage; however, it may cause diarrhea in 20% of patients and is one of the commonly used agents responsible for antibiotic-associated colitis. Moxifloxacin and levofloxacin are potential alternatives that have the convenience of once-daily dosing.

Case 74-1, Question 3: What dose should be prescribed for N.P.?

The recommended dosage of dicloxacillin is 500 mg orally every 6 hours. The dosage for penicillin V is 250 to 500 mg orally every 6 hours; for oral clindamycin, the dosage is 300 to 450 mg every 6 hours. Because dicloxacillin is the drug chosen for N.P., a dosage of 500 mg orally every 6 hours is appropriate. The dose for doxycycline is 100 mg orally every 12 hours, and the dose for trimethoprim-sulfamethoxazole is one to two double-strength tablets orally every 12 hours. The recommended dose for moxifloxacin is 400 mg orally every 24 hours and for levofloxacin 500 mg orally every 24 hours.

Case 74-1, Question 4: What is the appropriate duration of therapy for N.P.?

Although the recommended duration of therapy for cellulitis is 5 days, treatment may be extended if clinical improvement is not seen.[2] A reasonable recommendation to the patient would be to

continue oral antibiotics for 2 to 3 days after the patient has become afebrile and has clinically improved. Counseling points for N.P. should be to expect a response within 1 to 2 days of therapy beginning (although erythema may persist longer) and to return for reevaluation if the condition does not improve or worsens during the next few days.

CASE 74-1, QUESTION 5: What further diagnostic evaluation should be undertaken for N.P.?

In otherwise healthy individuals, identification of the causative organism in cases of mild cellulitis is unnecessary. Needle aspiration, fine-needle aspiration biopsy, and punch biopsy identify the causative organism in only 20% to 30% of patients.[2] Appropriate empiric treatment is effective in most patients, and an attempt to isolate the organism does not improve the success of treatment and adds significantly to the cost of care. However, patients with moderate-to-severe purulent infection, patients who failed initial empiric therapy, patients who are immunocompromised, patients with potential joint or tendon damage, or patients with life-threatening infections requiring hospitalization may benefit from additional cultures. In these cases, blood cultures, a swab of the primary wound, and a needle aspiration or punch biopsy of the leading edge of the cellulitis should be obtained for Gram stain and culture before initiating antimicrobial therapy. Anaerobic cultures need to be drawn only when the wound contains necrotic tissue, is foul smelling, or crepitus is present. Even if wound and blood cultures are obtained, many infections will return culture-negative results (74%). Blood culture results are positive in ~5% of cellulitis cases. Culture information, in conjunction with clinical course, is used to modify subsequent treatment. Because N.P. has only a mild cellulitis, cultures are not required, and she should receive empiric therapy. In addition to systemic therapy, N.P. should be instructed to keep the area clean with soap and water (if an open wound is present) and to protect the area. Treatment of cellulitis should also include rest,

immobilization and elevation of the infected area, and surgical drainage or debridement, as required. The wound should be assessed daily for local tenderness, pain, erythema, swelling, ulceration, necrosis, and wound drainage.

Case 74-1, Question 6: Could topical antibiotics be used to treat N.P.'s cellulitis?

The value of topical antibiotics in treating skin infections is questionable.[11] Most topical antibiotics have not been evaluated in appropriately designed trials. Although mupirocin is superior to placebo in treating some types of wound infections, its value in more severe disease is uncertain. In patients with moderate-to-severe infections, mupirocin, or any topical antibiotics (neomycin, bacitracin, polymyxin B) should not be used to replace or augment systemic antibiotics. Topical antibiotics likely do little but add to the cost of therapy, and they occasionally cause a contact dermatitis. Therefore, N.P. should not be treated with topical antibiotics because her cellulitis should be managed adequately with systemic antimicrobial therapy.

CASE 74-2

Question 1: O.A., a 49-year-old male, presents to the ED with a 3- to 4-day history of increasing pain around his left hip, secondary to an injury he sustained falling on the sidewalk. Examination reveals a swollen, warm, and extremely tender hip. O.A. has a temperature of 103.64 °F (39.8 °C). He is diagnosed with moderate cellulitis and is hospitalized to receive IV antibiotics. O.A. has no other underlying medical problems.

What empiric antibiotic regimen would be reasonable for O.A.?

The parenteral agent of choice in this case is nafcillin or oxacillin.[2]

Cefazolin (1–2 g IV every 8 hours) would be an appropriate alternative if it is less expensive than nafcillin. Second- and third-generation cephalosporins (cefuroxime, ceftriaxone, cefotaxime) and some quinolones may be as effective as nafcillin, but provide no

clinical advantages for most cellulitis. Patients with risk factors for MRSA (penetrating trauma, history of MRSA, nasal colonization, IV drug abuse, presence of systemic inflammatory response syndrome) should be treated with vancomycin or agents with activity against *Streptococci* and MRSA. One potential option is linezolid, but its use is limited by the potential for drug–drug interactions with serotonergic agents. Other agents include daptomycin, telavancin, dalbavancin, oritavancin, ceftaroline, and delafloxacin. Although these agents are as effective in severe cellulitis, they are not used as commonly as vancomycin because of cost and formulary availability.

Therefore, O.A. should receive nafcillin, oxacillin, or cefazolin, whichever is less expensive and more tolerable for the patient. Once O.A. has become afebrile and has evidence of clinical improvement, the parenteral antibiotic should be discontinued, and appropriate oral therapy should be initiated to complete at least a 5-day course (or longer until clinical improvement is seen).

Case 74-2, Question 2: Two days after starting therapy, O.A. develops a maculopapular skin rash. What alternative therapy should be chosen?

Regardless of when during the course of therapy a drug rash occurs (early or late), the precipitant drug should be discontinued because there is a chance, although small, that the reaction could worsen. In patients who have a penicillin allergy and who still require parenteral therapy, clindamycin, vancomycin, linezolid, moxifloxacin, levofloxacin, or delafloxacin could be chosen. Because all of these agents are equally effective, the choice should be based on cost and dosing convenience and presence of risk factors for MRSA.

Case 74-2, Question 3: After 48 hours of therapy, culture and sensitivity results are available. What changes, if any, should be made in O.A.'s treatment?

If culture results show only streptococcus species in a patient who is not allergic to penicillin, therapy should be de-escalated to

penicillin because it is effective, well tolerated, and less expensive than is nafcillin. If cultures grow staphylococcus species (*S. aureus*) that are sensitive to methicillin/oxacillin, the initial empiric therapy should be continued. If the organisms are resistant to methicillin/oxacillin, therapy should be switched to vancomycin 15 mg/kg IV every 12 hours or an alternative agent as previously described. Because O.A. has a presumed penicillin allergy (due to maculopapular rash) and does not require therapy for MRSA, he should continue with clindamycin or vancomycin. Cefazolin may also be an option for penicillin-allergic patients who do not experience severe allergic reactions, such as urticaria and anaphylaxis.

Case 74-2, Question 4: After 72 hours of therapy, O.A. has improved considerably and has been afebrile for 24 hours. Can he be switched to oral therapy?

Once O.A. has been afebrile for at least 24 hours and has significantly improved, he can be switched to oral therapy, if tolerated. Clinicians should select the oral agent on the basis of culture results (if available), anticipated pathogens (if no culture results), convenience, and cost.

Case 74-2, Question 5: What is the role of anti-inflammatory agents as adjunctive treatment of cellulitis?

Anti-inflammatory agents, such as nonsteroidal anti-inflammatory agents and corticosteroids, have been shown to decrease the time to resolution of cellulitis when given in conjunction with antibiotics to patients without diabetes.[2] Although supporting evidence is weak, a significantly quicker resolution of symptoms in patients on prednisolone 5 to 30 mg/day has been seen.[2,12,13]

CASE 74-3

Question 1: M.C. is a 22-year-old college football player who presents to the emergency department (ED) with a 3- to 4-day history of pain in his left thigh.

On examination, he has a swollen, erythematous, and purulent 2 × 3 cm abscess in the inner left thigh. The area is warm and tender to the touch. M.C. is afebrile with no signs of lymphangitis.

What tests are needed to confirm the diagnosis?

In patients with abscesses, large furuncles (superficial skin abscess), and carbuncles (clusters of furuncles), Gram stain and culture of pus is recommended; however, typically, patients may be adequately treated without further testing.[2] M.C. has risk factors for CA-MRSA (competitive athlete); if CA-MRSA is identified, infection control measures should be implemented to prevent an outbreak.[14] In febrile patients, blood cultures should be drawn before antibiotics are started to maximize the ability to isolate the pathogen.

Case 74-3, Question 2: Are the suspected organisms in M.C. similar to those found in other patients with cellulitis?

Abscess, furuncles, and carbuncles are most commonly caused by staphylococci, predominately *S. aureus.*[2,6] Abscesses may also be polymicrobial. For patients who are IV drug abusers and present with abscess or cellulitis, the infecting bacteria are similar to those found in normal hosts. IV drug use is also a risk factor for infection with CA-MRSA, and this should be particularly considered if the patient has had recurrent infections or has failed to respond to methicillin-sensitive *Staphylococcus aureus* (MSSA)-directed antibiotic therapy.[14] Although *S. epidermidis,* gram-negative organisms, including *P. aeruginosa,* and anaerobes are rarely pathogens, they may be present, particularly in patients who do not respond to initial therapy.

Case 74-3, Question 3: What is the appropriate empiric therapy for M.C.?

Antibiotic therapy is often not required. Incision and drainage should be performed for all abscesses, large furuncles, and carbuncles.[2] Antibiotics may be considered as an adjunct to incision

and drainage when systemic inflammatory response syndrome is present but has not been shown to improve cure rates in patients with cutaneous abscess. Antibiotic therapy should be directed toward suspected CA-MRSA and based on the severity of infection. Mild-to-moderate infection can be adequately treated with doxycycline or sulfamethoxazole/trimethoprim, whereas more severe disease should be empirically treated with agents such as vancomycin, daptomycin, linezolid, telavancin, or ceftaroline.[2,14] Several newer agents have been approved for the treatment of drug-resistant *S. aureus* infections; however, their current role in clinical therapy is not yet clear. If treatment does not result in some resolution of inflammation within 48 hours, antimicrobial coverage should be expanded to cover gram-negative organisms and resistant streptococci.

ERYSIPELAS

Erysipelas is a superficial skin infection caused by streptococci, predominantly group A, although groups C and G (and group B in children) also may cause the infection.[15,16] This skin infection affects ~1 in 1000 persons/year and is associated with diabetes mellitus, chronic venous insufficiency, and cardiovascular disease.[16] Erysipelas is diagnosed based on characteristics of the skin lesion and concurrent systemic symptoms.[15] The lesion is a continuous, indurated, edematous area, with a clearly defined raised edge.[16] Early in the course, the lesion is bright red, but it may turn to brown as the lesion ages or grows. The initial lesion results from a small break in the skin that becomes infected, although signs of the initial wound often are not evident. Aspiration of the lesion or a superficial swab is not recommended because this has not been shown useful in detecting the pathogen.[15] Patients with erysipelas have associated systemic symptoms of high fever, chills, frequent history of rigors, and general malaise. This constellation of systemic symptoms differentiates erysipelas from other local skin disorders.

CASE 74-4

Question 1: D.D., a 70-year-old male, presents to the ED with a red, swollen face. He describes the area as "a swollen red spot" that has appeared during the past 2 days. He also describes feeling unwell for the previous 3 days and having a fever. On examination, D.D. has a bright red, shiny, edematous lesion on his right cheek that is 0.4 cm wide. It is a continuous lesion with a clearly demarcated border.

What antibiotic therapy should D.D. receive?

Erysipelas responds promptly to antibiotics with activity against group A streptococci.[17] Oral penicillin V 250 to 500 mg every 6 hours and in severe cases parenteral penicillin G (2–4 million units IV every 6 hours) generally reduce the systemic symptoms (eg, fever, malaise) within 24 to 48 hours[17]; however, it will take several more days for the skin lesion to resolve. If D.D.'s condition does not improve within 72 hours of initiation of antibiotics, he should be instructed to return for reassessment. If D.D. has an allergy to penicillins, then a macrolide, clindamycin, or an oral fluoroquinolone, such as moxifloxacin, is a reasonable alternative.[15],[17] Ceftriaxone may also be an alternative in patients who are allergic to penicillin (without anaphylaxis) because of low (<3%) cross-sensitivity risk.[18] If the community has increased macrolide resistance to group A streptococci, these agents should not be part of empiric therapy. Antibiotic therapy should be continued for 10 days even if signs and symptoms resolve quickly to avoid a relapse, which could lead to chronic infection or scarring.

SKIN AND SOFT TISSUE INFECTIONS IN DIABETES

Skin and soft tissue infections are common in patients with diabetes mellitus. Approximately 25% of patients with diabetes report a history of skin and soft tissue infections, and 5% to 15% of patients with diabetes may undergo limb amputation.[19] In addition to the cost

associated with treating skin and soft tissue infections, functional disability may occur, which can significantly decrease the patient's quality of life. Patients with diabetes are at particular risk for foot problems, primarily because of the neuropathies and peripheral vascular diseases associated with long-standing diabetes. The decreased pain sensation allows the patient to continue to bear weight in the presence of skin damage, thereby promoting the formation of an ulcer. In addition, minor trauma (eg, cuts, foreign body insertion) can go unnoticed and, when left untreated, can become infected and extensive. Although these infections are common, preventive measures could reduce the frequency of amputations. Mild infections can be treated empirically with those agents used for soft tissue infections in patients with diabetes because these are commonly caused by aerobic gram-positive cocci. In moderate-to-severe infections, antibiotic coverage should be expanded because multiple organisms may be responsible for the infection. Although it is often difficult to differentiate colonizers from true pathogens, an average of two to six organisms are cultured from foot ulcers in patients with diabetes.[19,20] The following organisms (in no particular order) have been isolated in >20% of diabetic wounds: *S. aureus, S. epidermidis,* other streptococci, *Enterococcus faecalis, Proteus* species, *E. coli, Klebsiella* species, *Peptococcus* species, *Peptostreptococcus* species, and *Bacteroides* species.[19] Although these infections are often polymicrobic, empiric treatment can be effective even if not all cultured pathogens are covered.[19] To determine the true pathogens in the wound most accurately, a specimen of infected deep tissue (vs superficial swab), or cultures of purulent exudate or curettage should be obtained after the wound has been cleaned.[18] Although antibiotics have an important role, drainage and surgical debridement to remove necrotic tissue are essential.[19] Although anaerobic organisms often are difficult to culture, they must be considered if an abscess or devitalized, necrotic, foul-smelling tissue is present.

CASE 74-5

Question 1: T.U. is a 67-year-old male with diabetes presenting to his general practitioner for a routine checkup and has no specific issues to report. T.U. has a 15-year history of poorly controlled type 2 diabetes and a 3-year history of recurrent foot ulcers. On examination, the physician observes that an ulcer on the underside of the foot, which had previously healed over, is open and inflamed; purulent fluid can be expressed from the wound. T.U. reports no pain around the area and was unaware that the ulcer had worsened. He is currently febrile, and physical examination reveals mild lymphadenopathy and elevated white blood cell count.

Does T.U. have an active infection, and is antibiotic therapy required?

All open wounds, in patients with diabetes and those without, will become colonized with bacteria, but only infected wounds should be treated with antibiotic therapy.[19],[20] Often, it is difficult to determine whether an open wound is infected, but signs and symptoms (eg, purulent drainage, erythema, pain, and swelling around the area) are suggestive of infection. Based on his symptoms, T.U. has an infection that requires treatment.

Case 74-5, Question 2: What treatment should T.U. receive?

Before initiating antibiotic therapy, the presence of a clinically infected wound must first be confirmed because often diabetic wounds may not be infected and thus do not require antimicrobial therapy. When determining appropriate antibiotic therapy for infected wounds, clinicians must consider the severity of infection (mild vs moderate to severe), the patient's risk factors for MRSA or *P. aeruginosa* or if the patient has received any antibiotics within the past month. Mild diabetic foot infections should not be treated with topical antibiotic preparations because of limited evidence of their efficacy, insufficient penetration of antibiotic into the tissues, and potential detriment to wound healing.[21] Mild infections can be treated empirically in a way similar to that of other soft tissue infections because these are commonly caused by aerobic gram-positive cocci.[19] A penicillinase-resistant penicillin (eg, dicloxacillin) or cephalexin will be effective in most cases. The choice between these

agents should be based on tolerability and cost. Alternative agents include clindamycin, amoxicillin/clavulanate, or levofloxacin. If anaerobes are suspected (based on malodorous aroma, if the infection is severe or long-standing or has recently been treated with antibiotics), clindamycin or amoxicillin/clavulanate monotherapy can be used, or metronidazole can be added to the regimen.[18] If metronidazole is selected, concurrent use of an antibiotic with good activity against aerobic pathogens is required (eg, levofloxacin) because metronidazole has no activity against aerobic bacteria. In patients with significant vascular compromise, crepitus (gas in the subcutaneous tissues), or gangrene (dead tissue), a radiograph should be taken to identify any bone involvement suggestive of osteomyelitis.

For treatment of moderate-to-severe infections, oral or parenteral antibiotics (IV recommended for severe) with a broad spectrum of activity against gram-positive and gram-negative organisms should be selected based on suspected organisms. For staphylococci, streptococci, and enterobacteriaceae, therapeutic options include levofloxacin, cefoxitin, ceftriaxone, ampicillin/sulbactam, moxifloxacin, ertapenem, and imipenem/cilastatin.[20],[21] Levofloxacin and ceftriaxone have no anaerobic coverage; thus, clindamycin or metronidazole should be added if anaerobes are suspected (ischemic or necrotic wounds).[22] It is important to consider that clindamycin may be more likely to cause *Clostridioides difficile*–associated diarrhea.

Antibiotic selection should include coverage against MRSA or *P. aeruginosa* when risk factors are present. Infections due to MRSA can be treated with vancomycin, daptomycin, or linezolid. Newer antibiotics, including dalbavancin, telavancin, oritavancin, ceftaroline, and delafloxacin have activity against MRSA skin and soft tissue infections, but there is a lack of efficacy data in diabetic foot infections.[23] Infections due to *P. aeruginosa* may be more common in patients in areas with high local prevalence, warmer climates, and frequent exposure of foot to water, and can be treated with piperacillin/tazobactam. Other antibiotics with activity against *P. aeruginosa* include cefepime, ceftazidime, aztreonam,

imipenem/cilastatin, meropenem, doripenem, or an antipseudomonal fluoroquinolone (eg, ciprofloxacin). Aminoglycosides are associated with serious toxicity if used for an extended period and should probably be avoided in patients with diabetes.

Because T.U. is an elderly patient with diabetes with systemic signs and symptoms of infection (moderate to severe), empiric therapy with cefoxitin, ceftriaxone, ampicillin/sulbactam, levofloxacin, moxifloxacin, or ertapenem would be appropriate because he does not have risk factors for MRSA or *P. aeruginosa* infection.

CASE 74-5, QUESTION 3: Despite aggressive antibiotic therapy and debridement, T.U.'s infection spreads, and an amputation is required. How long should antibiotics be prescribed for T.U. after surgery?

Antibiotics may be continued until signs and symptoms of infection have resolved. Typical treatment duration is 1 to 2 weeks; however, longer treatment duration (2–4 weeks) may be necessary in patients with moderate-to-severe infections or in patients with infections that are slow to resolve.[20] Oral therapy should be considered once the patient has clinically improved; treatment can be stopped even if the underlying ulcer has not completely healed.[18,20]

The best option for uncontrollable, life-threatening infections often is amputation to remove the infected area. Once the infected area has been removed, antibiotic therapy should be continued for 2 to 5 days.[20]

CASE 74-5, QUESTION 4: What measures could have been taken to prevent this complication in T.U.?

Many of the foot problems associated with diabetes can be prevented with proper foot care (**Table 74-2**), and these preventive measures must be emphasized. Patients with diabetes with neuropathies or those who are elderly should carefully examine their feet every 1 to 2 days.

Table 74-2

Foot Care for the Patient With Diabetes

Inspect feet daily for cuts, blisters, or scratches. Pay particular attention to the area between the toes and use a mirror to examine the bottom of the foot.
Wash feet daily in tepid water and dry thoroughly.
Apply lotion to feet to prevent calluses and cracking.
Ensure that shoes fit properly (not too tight or too loose) and inspect them daily.
Trim nails regularly, making sure to cut straight across the nail.
Do not walk barefoot.
Do not use chemical agents to remove corns or calluses.

Necrotizing Soft Tissue Infections

Skin and soft tissue infections are described as *necrotizing* when the inflammation is rapidly progressing and necrosis of the skin or underlying tissue is present. The following clinical signs suggest necrotizing infections, as opposed to simple cellulitis: edema beyond the area of erythema, skin blisters or bullae, localized pallor or discoloration, crepitus, and the absence of lymphangitis and lymphadenitis. Common clinical features include high temperature, disorientation, lethargy, or the hard wood feel of the infected area.[2] Occasionally, a broad erythematous track along the route of infection may be present. Necrotizing soft tissue infections can progress rapidly, causing additional local effects (eg, necrosis and loss of skin sensation) and severe systemic effects (eg, hypotension, shock).[24] Necrotizing soft tissue infections are rare, with ~1000 cases/year in the United States, but they can be lethal.[25],[26] Necrotizing infections can occur in healthy individuals but are more commonly associated with IV or subcutaneous injections of illicit drugs.[27]

Necrotizing cellulitis involves the skin and subcutaneous tissues. Necrotizing fasciitis involves both superficial and deep fascia, and necrotizing infections involving the muscle are termed *myonecrosis.*

Group A β-hemolytic streptococci, *S. aureus,* other staphylococci, *Pseudomonas* species, other gram-negative organisms, *Clostridium perfringens, Peptostreptococcus*, *B. fragilis,* and *Vibrio* species can cause necrotizing infections.[24],[28] Gas gangrene is myonecrosis caused by a *Clostridium* subspecies, most commonly *C. perfringens* (70%).[24] Gas in a wound is not necessarily indicative of gas gangrene caused by *C. perfringens.* Gram-negative organisms (eg, *E. coli, Proteus* species, *Klebsiella* species) or anaerobic streptococci can produce gas in a wound. Air also could have been introduced at the time of the injury. Gas gangrene is characterized by acute onset of worsening pain that is usually out of proportion to the degree of injury. The primary treatment for necrotizing soft tissue infections involves extensive debridement of the area to remove all necrotic tissue and drainage. Early fluid resuscitation and broad-spectrum antibiotics are also imperative.[25]

CASE 74-6

QUESTION 1: M.T., a 45-year-old alcoholic homeless male, presents to the ED with a broken nose and facial lacerations, which he received after a fight outside one of the local taverns. On examination, in addition to the facial wounds, an area of severe inflammation, erythema, and necrosis is evident on his left calf. The area is very painful, crepitation is felt over the area, and a purulent discharge is present. M.T. states he believes the infection is because of a knife wound he experienced ~1 week ago.

What antibacterial treatment should be provided?

A Gram stain and culture of the purulent discharge should be ordered before initiating antimicrobial therapy. Because crepitus is present, the area should be incised, and a specimen of the infected tissue should be obtained for Gram stain and culture. Because the presence of crepitus may suggest a necrotizing infection, an immediate surgical consultation will be required for M.T. Pending the surgical evaluation, fluid resuscitation and IV antibiotics should be initiated. Gas in the tissues could be caused by many organisms, and empiric broad-spectrum antibiotic therapy with coverage against gram-positive organisms, enterobacteriaceae, and *B. fragilis* should

be started. Initial therapy should consist of an antibiotic with activity against MRSA (eg, vancomycin, daptomycin, or linezolid) plus either piperacillin/tazobactam, ampicillin/sulbactam, or ertapenem.[2] Clindamycin is often added for suspicion of group A streptococci, not for its antibacterial effects but because it inhibits protein synthesis, which may reduce toxin expression by the bacteria and cytokine response by the host.[2,29] Alternative options include ceftriaxone plus metronidazole, or a fluoroquinolone plus metronidazole. If a Gram stain of the infected tissue clearly shows the predominance of gram-positive cocci, consideration of narrowing the spectrum of antibiotic therapy is appropriate. Flesh-eating disease is usually a necrotizing fasciitis caused by virulent strains of group A streptococci. High-dose penicillin G (3 million units every 4 hours) plus clindamycin (900 mg IV every 8 hours) are the drugs of choice for this condition, as well as for gas clostridial myonecrosis.[2,29]

Potential adjunctive therapy for streptococcal necrotizing skin infections includes IV immunoglobulin G (IVIG) 2 g/kg as a single dose or 0.4 g/kg daily for 2 days. Alternative dosage regimens have included 1 g/kg on day 1 with 0.5 g/kg on days 2 and 3.[30] No clinical trials have proved the definitive benefit of IVIG, and the optimal dose, if used, is unknown. If it truly provides benefit, IVIG is thought to work by binding to the superantigens released by the streptococcal bacteria that are involved in the systemic effects of the infection.[30,31]

ANIMAL BITE WOUNDS

Any wound caused by an animal that results in the skin being cut or punctured should be examined to ensure no underlying tissue damage has occurred. This is especially true in patients with bites on the hand or around other joints. The wound should be washed thoroughly with clean water as soon as possible after the bite.[32] Irrigation of the wound, including puncture sites, should be extensive

to reduce the risk of infection. Obtaining specimens for cultures is not required, and wound irrigation should begin as soon as possible.

Animal bites may develop bacterial infections due to aerobic or anaerobic organisms in up to 18% of cases.[33] Purulent wounds or abscesses likely contain mixed aerobic and anaerobic organisms, whereas nonpurulent wounds are more frequently caused by streptococci or staphylococci.[2] *Pasteurella multocida* is a commonly isolated pathogen and is particularly significant in cat bites because it is present in up to 75% of the oral flora of cats.[2],[33] Although antibiotic treatment is not required for some dog bites, reports of a >75% incidence of infection after cat bites suggest that all patients with cat bites should receive antibiotics.[32]

CASE 74-7

QUESTION 1: P.J., an 18-year-old male, presents to the ED 3 hours after being bitten on the leg by a neighbor's dog. He has a laceration, 14 cm long, on his medial calf. Four distinct puncture marks, suggestive of teeth marks, also are present on the calf. P.J. was healthy before the attack and has no chronic illness.

Should P.J. receive any treatment other than suturing of his laceration?

The standard of care for all bites involves wound irrigation and decontamination of the wound.[32] P.J.'s wound should be evaluated for deep tissue injury, devascularization of any tissue, and bone injury. Loose suturing or closure with adhesive strips is appropriate for lacerations after irrigation.[32]

CASE 74-7, QUESTION 2: Because P.J. has several punctures that are difficult to irrigate, he is a candidate for prophylactic antibiotic therapy. Which antibiotic(s) should he receive?

The need for antibiotics is controversial and guided by wound severity and patient immunocompetency.[2],[33] The patient should receive a prophylactic course of antibiotics if the wound involves the hand or is near joints, if it involves deep punctures or is difficult to

irrigate, if the patient is immunocompromised (eg, diabetes, splenectomy), or if the wound is not well perfused. Antibiotics are not required for dog bites in which no deep tissue injury is present, and the wound can be well irrigated, particularly if the wound is on the lower extremities in healthy adults or children.[32]

The selection of the appropriate antibiotic is based on the most likely pathogens from the specific animal bite. Although *P. multocida* often is considered the primary pathogen of dog bites, antibiotic coverage also must address the other common pathogens. Monotherapy with amoxicillin/clavulanate 875/125 mg orally every 12 hours is recommended.[2],[32] Alternative options include second-generation cephalosporins (eg, cefuroxime plus an agent with anaerobic coverage such as clindamycin or metronidazole) or cefoxitin alone. If the patient is allergic to penicillin, doxycycline, moxifloxacin, or a carbapenem (eg, ertapenem) provides adequate coverage.[2] In all cases, patients should be instructed to watch for improvement; if the wound does not heal or it worsens within 48 hours, the patient needs to be reevaluated. Prophylactic antibiotic treatment should not extend beyond 5 days unless signs of an infection have occurred. If the patient presents with an established infection, parenteral therapy is warranted if the infection is over a joint, has lymphatic spread, or involves the hand or head. Parenteral therapy should be continued until the infection has resolved, and therapy should then be continued with oral antibiotics for at least 7 days or until all clinical signs of the infection have resolved.

Prophylaxis for rabies is required only if the animal is from an area with endemic rabies or if the bite was the result of an unprovoked attack by a wild animal.[32] The local health board should be contacted to determine the recent rabies risk in the area. In addition, immunization status of the animal should be obtained, if possible. If P.J. has not received a tetanus toxoid booster within the past 5 years, a booster should be administered. If P.J. has never been immunized for tetanus, tetanus immune globulin should be administered in addition to the tetanus toxoid.

HUMAN BITE WOUNDS

CASE 74-8

QUESTION 1: C.K., a 40-year-old male, presents with a sore arm 24 hours after receiving a bite to his left forearm by his neighbor in a "discussion over property boundaries." C.K. was previously healthy and has no chronic diseases. A 6 × 8 cm area of his left forearm is swollen and erythematous and includes several distinct puncture marks consistent with a human bite. No joint deformity or bone abnormality is detected on clinical examination.

How should C.K. be treated?

Treating a human bite is similar to that of any other laceration, including cleansing, irrigating, exploring, debriding, draining, excising, and suturing, as required.[32] All human bites should be cleansed as soon as possible, and any lacerations or punctures irrigated copiously. Surgical exploration with debridement, drainage, or excision should be undertaken in case of potential injury of deeper tissues or pus collection. If there is evidence of pus accumulation, the area should be explored and drained. C.K. should receive systemic antibiotic therapy to eradicate potential infecting organisms. If the wound is severe (ie, involves subcutaneous tissues, a joint, or a large area) or if the patient is unlikely to be compliant with oral antibiotics, parenteral administration of antibiotics is required. The most common pathogens in human bites are β-hemolytic streptococci, *S. aureus, Eikenella corrodens, Fusobacterium, Peptostreptococcus, Prevotella*, *Porphyromonas* spp., and *Corynebacterium* subspecies.[2] Treatment with amoxicillin/clavulanate, ampicillin/sulbactam, or ertapenem is appropriate. For patients who are allergic to penicillin, alternatives include ciprofloxacin or levofloxacin plus metronidazole or moxifloxacin alone.

Prevention and Treatment of Infections in Neutropenic Cancer Patients

Richard H. Drew and Steven W. Johnson

CORE PRINCIPLES	CHAPTER CASES
DEFINITIONS	
1 As a consequence of select cancer chemotherapies, patients may experience neutropenia (defined as an absolute neutrophil count <500 cells/μL or anticipated to drop <500 cells/μL within 48 hours) and fever (defined as a single oral temperature of ≥101 °F [38.3 °C] or a temperature of ≥100.4 °F [38.0 °C] for >1 hour).	**Case 75-1 (Question 4)**
2 Bacteria are the primary pathogens associated with infection in patients with	**Case 75-1 (Questions 1, 6)**

	febrile neutropenia (especially those occurring early); however, fungal pathogens and reactivation of viruses may be a concern in select patient populations.	
CLINICAL PRESENTATION OF FEBRILE NEUTROPENIA		
1	Fever is usually the earliest (and often the only) sign of infection.	**Case 75-1 (Question 4)**
	A systematic assessment should be performed to maximize the chances of establishing a clinical and microbiologic diagnosis that may determine antimicrobial choice and prognosis.	**Case 75-1 (Question 5)**
2	Before antibiotics are initiated, two sets of blood cultures (with each set consisting of two culture bottles) should be obtained. Additional site-specific cultures should also be obtained if such infections are suspected. A complete blood count, comprehensive metabolic panel, coagulation, urinalysis, and assessment of organ function (eg, liver and kidney function) should be assessed.	**Case 75-1 (Question 5)**
KEY PREVENTION INFORMATION		
1	Antibiotic prophylaxis with a fluoroquinolone is recommended for patients who are at high-risk for febrile neutropenia or profound, protracted neutropenia (eg, most patients with	**Case 75-1 (Question 2)**

	acute myeloid leukemia/myelodysplastic syndrome [AML/MDS], or hematopoietic stem cell transplantation [HSCT] treated with myeloablative conditioning regimens). Antibiotic prophylaxis is not routinely recommended for patients with solid tumors.	
2	Antifungal prophylaxis is recommended with an oral triazole or parenteral echinocandin for patients who are at high risk for febrile neutropenia or profound, protracted neutropenia. Antifungal prophylaxis is not routinely recommended for patients with solid tumors. The choice of the agent depends largely on the risk of mold infections.	**Case 75-1 (Question 3)**

KEY TREATMENT INFORMATION

1	Risk stratification should be undertaken to identify patients most likely to experience significant infection-related complications. Patients at highest risk include those with prolonged (>7 days) and profound (<100 cells/μL) neutropenia or select comorbidities (hypotension, severe mucositis interfering with swallowing or causing diarrhea, pneumonia, new-onset abdominal pain, hepatic or renal insufficiency, or neurologic changes).	**Case 75-1 (Question 7)**
2	In the absence of evidence of site- or pathogen-specific etiologies or clinical	**Case 75-1 (Questions 7–9)**

	instability, typical initial empiric therapy for high-risk individuals is monotherapy with an intravenous antipseudomonal β-lactam, such as cefepime, a carbapenem (eg, imipenem–cilastatin or meropenem) or piperacillin–tazobactam. Additional agents may be added (eg, vancomycin, an aminoglycoside, or fluoroquinolone) to initial therapy in high-risk patients for management of complications (eg, hemodynamically unstable, or pneumonia). Antiviral therapy is generally restricted to patients with serologic or clinical evidence of active viral infection. For low-risk individuals managed in the outpatient setting, consideration of an oral antibiotic regimen such as ciprofloxacin plus amoxicillin-clavulanate is commonly utilized. The first dose of empiric therapy should be administered within 1 hour of triage from initial presentation.	**Case 75-2 (Questions 1–5)** **Case 75-4 (Question 4)**
MONITORING PARAMETERS		
1	The need for (and timing of) modification of the initial empiric therapy is dependent on the risk group (ie, low vs high risk), establishment of an infection site or causative pathogen, persistence or resolution of fever, and clinical stability.	**Case 75-2 (Question 6)** **Case 75-4 (Question 3)**
2	Highest risk patients unresponsive to initial empiric antibacterial therapy	**Case 75-3 (Questions 1, 2)**

	should be considered for the addition of antifungal therapy at days 4 through 7. In addition to coverage for *Candida* species, highest risk patients with persistent or recurrent fever after 4 to 7 days of appropriate antibacterial therapy with prolonged (ie, >10 days) neutropenia should be considered for antimold therapy. Low-risk patients who are clinically stable do not routinely need antifungal therapy.	**Case 75-4 (Questions 1, 2, 4)**
THERAPEUTIC CONTROVERSIES		
1	Although hematopoietic colony-stimulating factors prevent neutropenia in high-risk patients with cancer, use of these agents as treatment of febrile neutropenia unresponsive to antibiotics remains controversial.	**Case 75-1 (Question 3)** **Case 75-4 (Question 5)**

INTRODUCTION

Many patients with both solid tumor and hematologic malignancies have had their lives prolonged through therapeutic advances in chemotherapy, immunotherapy, and hematologic stem cell transplantation (HSCT). Despite such advances, infectious complications continue to be a major cause of morbidity and mortality in these patients. Risk assessment, prevention, rapid detection, and effective management of infections, although a major challenge, can lead to improved outcomes in such immunocompromised hosts.[1,2]

This chapter focuses on infectious complications in patients with immunosuppression as a consequence of cancer. The following

topics are addressed: risks and epidemiology of infection, principles of prophylactic antimicrobials, empiric initial antibacterial selection, modification and duration of therapy, empiric antifungal and antiviral use, and the use of hematopoietic growth factors.

RISK FACTORS FOR INFECTION

Patients are rendered immunocompromised when there is a significant disruption or deficiency of one or more of the host defenses as a result of the underlying disease or chemotherapy. These risk factors include neutropenia and impairment in both humoral (antibody and complement) and cell-mediated immune defenses. In addition, disruption of barriers to infection resulting from chemotherapy-related damage to skin and mucosal barriers further increases the risk of infection. As a result, bacteria, fungi, and (less commonly) protozoa and viruses may infect various sites depending on the specific immunodeficiency.

Neutropenia

Granulocytes, or granular leukocytes, represent an important defense against bacterial and fungal infections. *Neutropenia* (a reduction in the number of circulating granulocytes or neutrophils) predisposes the host to infections. The terms *granulocytopenia* and *neutropenia* are often used interchangeably. The degree of neutropenia is expressed in terms of the absolute neutrophil count (ANC) or the total number of granulocytes (polymorphonuclear leukocytes [PMNs] and band forms) present in the circulating pool of white blood cells (WBCs). For purposes of guideline development and clinical trials, neutropenia is most commonly defined as an ANC <500 cells/μL or <1000 cells/μL with an anticipated drop to <500 cells/μL within 48 hours.[3],[4] The risk, severity, and type of infection in the patient with neutropenia is proportional to the severity, rate of decline, and duration of neutropenia.[5] In general, the relative risk of

infection is low when the ANC is >1000 cells/μL, with the frequency and severity of infection inversely proportional to the ANC. As the ANC drops to <500 cells/μL, the risk of infection rapidly increases.[5,6] Conversely, recovery of the ANC is one of the most important factors determining the outcome of infectious complications in the patient with neutropenia. Febrile patients with short durations of neutropenia (≤7 days) or in whom neutropenia is not severe (<100 cells/μL) less frequently experience serious, life-threatening infections.[1,7] In contrast, patients with severe neutropenia lasting >7 days are at significant risk for infection.[1]

Damage to Physical Barriers

The intact skins and mucosal surfaces of the body (gastrointestinal [GI], sinus, pulmonary, and genitourinary) constitute the host's primary physical defense against microbial invasion. The integrity of this physical barrier may be disrupted by tumor, treatment (eg, surgery, radiation), or various medical procedures (eg, insertion of intravenous [IV] or urinary catheters, venipuncture, measurement of rectal temperature). Device-related infections, including those associated with central venous catheters, are commonly caused by migration of skin flora (eg, staphylococci) through the cutaneous insertion site. Infections secondary to damaged mucosal lining of the GI tract such as mucositis (usually secondary to chemotherapy or graft-versus-host disease [GVHD]) are usually caused by enteric bacteria and fungi such as *Candida* species.

Malignancy-Related Alterations in the Immune System

Malignancies such as leukemia (acute and chronic), lymphoma (eg, non-Hodgkin lymphoma) and myelodysplastic syndrome (MDS) may invade bone marrow, resulting in leukopenia. This is most notable in patients with advanced or refractory malignancy, which may reflect either bone marrow invasion or as a consequence of multiple

courses of immunosuppressive chemotherapy. In contrast, predisposition to infection in patients with solid tumors is often associated with anatomic abnormalities (eg, obstruction or erosion). Such risks may be enhanced as a consequence of surgery, chemotherapy, and/or radiation to correct the underlying tumor.

Patients with immunoglobulin (Ig) deficiencies (eg, hypogammaglobulinemia, chronic lymphocytic leukemia [CLL], or splenectomy) are at increased risk for infections with encapsulated bacteria, which undergo antibody opsonization for efficient phagocytosis. Such bacteria include *Neisseria meningitidis, Haemophilus influenzae*, and *Streptococcus pneumoniae*. Hodgkin's disease, organ transplantation, and human immunodeficiency virus (HIV) disease can disrupt the cellular immune system, increasing the risk of infections with obligate and facultative intracellular organisms such as mycobacteria, *Listeria*, *Toxoplasma*, viruses, and fungi. Certain hematologic malignancies and MDSs may also be associated with immunodeficiencies secondary to replacement of leukocytes with malignant cells.

Medications Impacting Host Defenses

Some chemotherapeutic agents (eg, fludarabine) have profound effects on both cellular and humoral defenses.[8,9] Corticosteroids exert their immunosuppressive effects on the cellular immune system, particularly at the T-lymphocyte and macrophage levels. Therefore, patients receiving corticosteroids (eg, HSCT recipients with GVHD) have increased susceptibility to viral, bacterial, protozoal, and fungal infections.[10] Infectious complications secondary to glucocorticoids are dose dependent. The risk of infection increases with daily doses >10 mg or cumulative doses >700 mg of prednisone or its equivalent.[10] Thus, patients receiving corticosteroids in either high doses (>20 mg prednisone or its equivalent daily) or for prolonged periods are at increased risk for infections caused by opportunistic pathogens. In addition, corticosteroids may blunt the usual signs of infection such as fever

and inflammation. Severe cell-mediated immunodeficiency may also be caused by GVHD and its treatment.[1,8] Chemotherapeutic monoclonal options (eg, alemtuzumab) significantly weaken the immune system, predisposing recipients to viral, bacterial, and fungal infections.[11,12]

Colonization or Prior Infection

Colonization is characterized as isolation of an organism from any particular site (eg, stool, nasopharynx) without clinical signs of infection. Most infections in patients with neutropenia are caused by either the host's endogenous microflora or hospital-acquired pathogens that have colonized the alimentary tract, upper respiratory tract, or skin. Therefore, microbial colonization can be a prerequisite to infection in patients with neutropenia. This is perhaps best studied in patients colonized with methicillin-resistant *Staphylococcus aureus* (MRSA). Prior infection (especially in the pre-engraftment phase of HSCT recipients) is a risk factor for infection during immunosuppression, particularly for viral infections (eg, cytomegalovirus [CMV], herpes simplex virus [HSV], and varicella zoster virus [VZV]). Infections with these pathogens during immunosuppression are generally considered to be a consequence of latent infection rather than of new infection.[1,2,8]

Hematopoietic Stem Cell Transplantation

Transplantation of bone marrow predisposes patients to the development of opportunistic infections secondary to both intensive immunosuppressive therapy and transmission.[8] These infections may be acquired or may represent reactivation of latent host infection. The introduction of new therapeutic approaches for treatment of the underlying malignancy (including nucleoside analogs and monoclonal antibodies to CD20 and CD52), along with use of unrelated stem cell donors, has increased the potential for infections in these patients.[8] When compared with autologous or

syngeneic HSCT recipients, patients with allogeneic HSCT have an increased risk of infection, particularly in those undergoing therapy for GVHD.[8] The pathogens causing infections vary with the time since transplantation. The use of immunosuppressives after transplantation (eg, corticosteroids, antithymocyte globulin, and alemtuzumab) also significantly increases the risk of infection.[8]

Radiation Therapy

Side effects associated with the use of radiation therapy for the treatment of malignancy (eg, mucositis, skin breakdown, or reduction in blood counts) also predispose a patient with neutropenia to infection.

Functional Asplenia

The spleen is responsible for the production of opsonizing antibodies, assisting in protection against encapsulated bacteria (eg, *S. pneumoniae, H. influenzae,* and *N. meningitidis*). Functional asplenia may occur secondary to irradiation or as a complication of GVHD.

MOST COMMON PATHOGENS

CASE 75-1

Question 1: B.C., a 41-year-old female, was admitted to the cancer center for placement of a central IV catheter for administration of chemotherapy to treat acute nonlymphocytic leukemia in relapse. She was diagnosed 2 years ago and was treated with cytarabine plus daunorubicin, which resulted in a complete remission for 33 months. This admission, she will be treated with high-dose cytarabine plus mitoxantrone for reinduction.

What are the most likely pathogens to cause infection in patients such as B.C. during periods of chemotherapy-induced neutropenia?

Bacteria are the primary pathogens associated with infection in patients with febrile neutropenia, especially those occurring early.[13] Bacteremia, reported in ~25% of patients with febrile neutropenia, is most often caused by aerobic gram-negative bacilli (including *Pseudomonas aeruginosa, Escherichia coli,* and *Klebsiella pneumoniae*) or aerobic gram-positive cocci (ie, coagulase-negative staphylococci, *S. aureus,* enterococci, viridans streptococci).[14] Since the mid-1990s, the proportion of gram-negative infections has decreased with a proportional increase in gram-positive infections.[1] Gram-positive bacteria now account for ~60% to 70% of microbiologically documented infections in neutropenic cancer patients.[3],[15] This is likely attributable (in part) to the frequent use of indwelling IV catheters, intensive chemotherapy, and widespread use of broad-spectrum antibiotics.

S. aureus (including MRSA) and coagulase-negative staphylococci, streptococci (including *S. pneumoniae* and viridans streptococci), and *Corynebacterium* species are increasingly important pathogens.[15] Moreover, enterococcal infections (including vancomycin-resistant enterococci [VRE]) are increasing in frequency. Meningitis caused by the intracellular organism *Listeria monocytogenes* can be observed in patients with defective cellular immunity caused by disease or prolonged corticosteroid use. In general, anaerobic bacteria are an infrequent cause of infection in patients with granulocytopenia having hematologic malignancies.[16] However, they should be suspected in patients with GI malignancies or with significant disruption of the GI tract.[16] *Clostridioides difficile* is another anaerobic pathogen that may cause infection in this population.

Pneumocystis jiroveci (formerly known as *Pneumocystis carinii* that causes *Pneumocystis carinii* pneumonia or PCP [now *Pneumocystis jiroveci* pneumonia or PJP]) is a pathogen responsible for lung infections primarily in patients with HIV infection. However, PJP can also be responsible for lung infections in some patients with cancer.[17],[18] Seen predominantly in patients with solid tumors or hematologic malignancies receiving long-term corticosteroids, PJP

may present as subacute, febrile, hypoxemic, and diffuse pulmonary involvement.[17],[18]

Invasive fungal infections (IFIs) are a major cause of morbidity and mortality among neutropenic cancer patients and patients undergoing HSCT.[19] The incidence of IFIs in patients with febrile neutropenia varies widely because of differences in definitions, methods of detection, patient populations, and prior use of antifungal prophylaxis. In general, patients with hematologic malignancies have a higher incidence of fungal infections than do those with solid tumors.[20] Similar to the risk of bacterial infections, the risk of IFIs is also related to the degree and duration of neutropenia. IFIs tend to occur later in the illness. Patients with prolonged neutropenia (>7 days) or with AML undergoing intensive induction therapy, allogeneic HSCT recipients, and those undergoing therapy for GVHD are at increased risk for acquiring systemic fungal infections.[19],[21] Up to 50% of patients who die during prolonged periods of neutropenia have evidence of deep-seated mycoses.[19] Before the use of fluconazole prophylaxis in selected populations, *Candida* species were responsible for most IFIs. Most fungal infections in neutropenic cancer patients are caused by *Candida* and *Aspergillus* species.[22–24] In addition to the risk factors mentioned earlier, specific risk factors for mold infections include, but are not limited to, older age, cytopenias, CVM disease, and iron overload. Other less common but important pathogenic fungi are those associated with zygomycosis (eg, *Mucor* and *Rhizopus* species) and other emerging pathogens (non-albicans *Candida, Trichosporon beigelii, Malassezia* species, *Cryptococcus neoformans,* and *Fusarium* species).[22–24] Today, invasive infections attributable to *Aspergillus* species and other molds are a major cause of IFI-related death (particularly in those with prolonged neutropenia and GVHD).[19],[25] Recent reports of improved survival from IFIs are likely related to newer prophylactic and treatment options and advances in cancer chemotherapy.[26]

As previously stated, most viral infections in neutropenic cancer patients are caused by a reactivation of latent infection rather than a new infection.[1],[2],[8] These may include hepatitis B virus (HBV), HSV, and VZV. Other viruses, such as CMV, can be either reactivation or

newly acquired during HSCT. The risk of viral reactivation in these patients increases in those who are seropositive before transplant. Respiratory viruses (eg, respiratory syncytial virus [RSV], influenza, parainfluenza), GI viruses (eg, rotavirus and norovirus), and other seasonal viruses may occasionally cause infection in this population.

STRATIFICATION FOR RISK OF INFECTION

Risk stratification to identify patients most likely to experience neutropenia has important implications for decisions about prevention, diagnostic strategies, empiric therapy (selection, route of administration, duration), and site of care.[1,8,27,28] In general, the underlying malignancy, status of disease (ie, active vs remission), degree and duration of neutropenia, and chemotherapy type (including select immune targeting agents) impact both risk intensity and pathogen(s). Patients at highest risk for complications include those with prolonged (>7 days) and profound (<100 cells/μL) neutropenia or with select comorbidities (hypotension, severe mucositis interfering with swallowing or causing diarrhea, pneumonia, new-onset abdominal pain, hepatic or renal insufficiency, or neurologic changes).[4] In contrast, patients with shorter (≤7 days) anticipated durations of neutropenia without significant comorbidities are generally considered at low risk for complications of infection.[2,4] Patients without fever but exhibiting new signs of infection should also be treated as high risk. Presenting signs and symptoms, cancer type, chemotherapy regimen, medical comorbidities, and prior history of febrile neutropenia (especially if severe or prolonged) should also be considered. Chemotherapeutic regimens associated with the highest (>20%) incidence are summarized in detail elsewhere[28] (see Section 16, Hematology and Oncology).

The factors impacting risk have been utilized by the consensus guidelines in assigning infection risk in patients with cancer as low, intermediate, and high. Other risk assessment tools have been

proposed,[1,2] including the Multinational Association for Supportive Care in Cancer (MASCC) Index.[29] Age of at least 60 years, presence of hematologic malignancies with a history of prior fungal infections, severe symptoms (particularly hypotension), inpatient site of care, organ dysfunction (hepatic and renal), and presence of chronic obstructive pulmonary disease are important variables that result in a low MASCC score (ie, <21), and (consequently) patients with any of these factors are considered at highest risk. Young patients (younger than 20 years) with solid tumors and no or mild symptoms (including the absence of hypotension) or organ dysfunction are generally at low risk for complications.

PROPHYLAXIS AGAINST INFECTION

Infection Control

CASE 75-1, QUESTION 2: Should B.C. receive antimicrobial prophylaxis during the neutropenic period? If yes, which agents should be used?

Exogenous contamination can be prevented by strict protective isolation of patients in specially designed rooms that maintain a sterile environment. These laminar airflow rooms are ventilated with air that is passed through a high-efficiency particulate air filter, which removes >99% of all particles >3 μm. Total protective isolation is accomplished by strict isolation in conjunction with the administration of sterile food and water, local skin care, and intensive microbial surveillance. However, this regimen is burdensome, difficult to accomplish, and expensive, and is recommended only for high-risk patients (ie, allogeneic HSCT recipients).[4] HSCT recipients and candidates undergoing conditioning therapy should avoid exposure to plants, flowers, and certain foods (eg, uncooked fruits and vegetables), which increase the risk of exposure to fungi.[8,30] Close attention and adherence to adequate handwashing procedures is

essential. In addition, contact isolation is advocated in circumstances in which the patient may be colonized or infected with resistant organisms (eg, MRSA, VRE, or multidrug-resistant gram-negative pathogens). Finally, isolating the patients from family or caregivers with potentially contagious respiratory viral illnesses is advocated.[27]

Antimicrobial Prophylaxis

Early administration of antimicrobials (ie, antibacterials, antifungals, and antivirals) during the afebrile, neutropenic period in select high-risk patients may result in a reduction in the number of febrile episodes and subsequent risk of infection. The goals of such prophylactic regimens are intended to reduce pathogenic endogenous microflora or prevent the acquisition of new microorganisms. The potential benefits of such prophylaxis must outweigh the risks of antimicrobial-related adverse effects including drug interactions, the development of resistance (including multidrug resistance most notable with antibacterials), disruption of the gut microbiome and the potential for superinfection. Use of agents for prophylaxis (ie, fluoroquinolones) may also preclude the use of the class as empiric therapy for subsequent suspected or documented infections.

In general, lowest risk patients with cancer (ie, those receiving standard chemotherapy for many solid tumors and whose neutropenia is anticipated to be <7 days) should not routinely receive antibacterial and antifungal prophylaxis.[27] Prophylactic administration of antivirals in such patients is generally restricted to those with a history of prior infection (eg, HSV). In contrast, highest risk patients (eg, allogeneic HSCT recipients and those with acute leukemia, receipt of alemtuzumab therapy, GVHD requiring high-dose steroids, and prolonged [>10 days] neutropenia) should receive antibacterial, antifungal, and (in select cases) antiviral prophylaxis.[27] PJP prophylaxis should also be considered in these patients.

ANTIFUNGALS

Case 75-1, Question 3: Should antifungal prophylaxis be used in B.C.? What is the role of hematopoietic growth factors?

The use of primary antifungal prophylaxis in patients with cancer having neutropenia should be reserved for those at intermediate or high risk for IFIs.[27] Patients with acute lymphocytic leukemia (ALL) receiving remission or salvage induction chemotherapy are at intermediate risk and should be considered for prophylaxis. Although autologous HSCT recipients may not routinely benefit from fungal prophylaxis (most notably those without evidence of mucositis), those with prolonged neutropenia, mucosal damage, or receipt of purine analogs should receive primary prophylaxis.[8] In patients for whom antifungal prophylaxis is indicated, the choice of the agent depends largely on the additional risk of invasive mold infection (eg, patients with AML/MDS, or those with GVHD receiving intensive immunosuppressive therapy regardless of neutropenia). Acceptable options for prophylaxis against *Candida* species include fluconazole and the echinocandin, micafungin (although caspofungin and anidulafungin would be considered interchangeable).[27] In the setting of colonization with fluconazole-resistant *Candida* species (ie, *C. krusei or C. glabrata*), an echinocandin is preferred.[8,27,31] In contrast, patients with higher risk factors for mold infections should be considered for prophylaxis with mold-active drugs (ie, posaconazole, voriconazole, echinocandins, or [less commonly] amphotericin B) during periods of risk.[8,27] Mold-active agents are also recommended in the setting of anticipated periods of prolonged (at least 2 weeks) neutropenia, or prolonged neutropenia immediately before HSCT.[27] Prophylactic use of antifungals may also be used in patients with a prior history of invasive disease due to *Candida* spp. or filamentous fungi. Such prevention (known as *secondary prophylaxis*) should be considered in these patients during subsequent chemotherapy or stem cell transplantation for the duration of immunosuppression.

Nonabsorbable antifungal agents

Nonabsorbable antifungal agents, such as oral nystatin,[32,33] clotrimazole,[34] and oral amphotericin B[35] have been studied. Although oral amphotericin B and clotrimazole reduce the frequency of oropharyngeal candidiasis, none of these antifungals has a role as primary prophylaxis in IFIs.[8] In attempts to enhance activity while minimizing side effects associated with IV administration, aerosolized delivery of amphotericin B deoxycholate (AmBd) has been investigated for the prevention of IFIs in this patient population,[36] and aerosolized liposomal amphotericin B (LAmB) has been used in patients with leukemia and HSCT.[37] Although promising, the optimal dose, delivery device, and duration of aerosol administration of amphotericin B preparations have not yet been determined.

Amphotericin B

The use of systemic antifungals for prophylaxis has been summarized elsewhere.[38] Many of the earlier studies evaluated the prophylactic role of IV amphotericin B.[39–41] In general, use of AmBd is limited in this setting because of its toxicities (ie, infusion-related reactions, nephrotoxicity, and electrolyte disturbances) relative to available options for prophylaxis. Consequently, amphotericin B is generally discouraged for primary prophylaxis in high-risk patients, unless the patient is unable to receive other mold-active prophylactic agents. If required, a lipid-based formulation would be preferred, especially in patients at increased risk for amphotericin B–induced nephrotoxicity.

Systemic azole antifungals

Systemic azole antifungals (eg, fluconazole, itraconazole, voriconazole, posaconazole) may also be considered in select patients, but differ considerably in their spectrum of activity, adverse reaction profile, drug interactions, and need for serum concentration monitoring. The newest member of this ciass, isavuconazole, represents potential advantages over comparator agents. Isavuconazole, approved for the treatment of invasive aspergillosis

and mucormycosis, is now considered an option for IFI prevention in patients undergoing allogeneic HSCT at intermediate or high risk of IFI.[42–44]

Fluconazole prophylaxis decreases the frequency of both superficial (eg, oropharyngeal candidiasis) and systemic fungal infections in HSCT recipients[45,46] but not in patients with leukemia.[7,47,48] Fluconazole is available as both oral and IV formulations, and its oral bioavailability is not significantly influenced by changes in gastric acidity. The IV formulation enables fluconazole to be administered to critically ill patients or patients who have difficulty swallowing. Relative to the alternate systemic azoles (itraconazole, voriconazole, and posaconazole), fluconazole is a less potent inhibitor of cytochrome P450 3A4 isoenzymes that may interact with select chemotherapeutic agents (such as vincristine). Historically, among the triazoles, fluconazole offers the most favorable pharmacokinetic profile (now challenged with the addition of isavuconazole). Fluconazole administration results in a predictable serum concentration, unlike other triazoles, which exhibit significant variability in drug concentration, most notably following oral administration. Consequently, serum concentration monitoring of these agents (itraconazole, voriconazole, posaconazole) may help ensure optimal drug exposure while reducing the potential for concentration-related toxicities. However, determination of definitive target concentrations for prophylactic use is hampered by the lack of controlled, prospective clinical trials. For itraconazole, steady-state trough concentrations of >0.5 μg/mL have been recommended. Voriconazole steady-state serum concentrations of >0.5–4 μg/mL have been recommended for use as prophylaxis. Studies regarding the optimal trough concentration of posaconazole for prophylaxis differ, but range between 0.5 and 0.7 μg/mL.[49,50] Adverse effects associated with fluconazole, similar to that of other triazoles include GI (nausea, vomiting, hepatic enzyme elevations) and cardiovascular (ie, QTc prolongation [shortening for isavuconazole]) effects. Although fluconazole is useful prophylactically, concern about its lack of reliable in vitro activity against molds limits its use in intermediate- and high-risk patients (notably those with neutropenia

and MDS, AML, or GVHD). An increased frequency of isolation of non-albicans *Candida* (eg, *C. krusei, C. glabrata, and C. parapsilosis*) has also been noted in some institutions.[51]

Itraconazole has been well studied as an antifungal prophylaxis. In addition to in vitro activity against many *Candida* species (eg, *C. albicans*), itraconazole is active in vitro against *Aspergillus* species and reduces systemic *Candida* infections.[52–54] Although itraconazole oral solution demonstrates improved bioavailability over the capsule formulation, it is associated with significant GI intolerance.[55],[56] Itraconazole is contraindicated in patients with reduced cardiac ejection fraction because of its negative inotropic effect. Use of newer azoles (such as posaconazole and voriconazole) has largely replaced the use of itraconazole for prophylaxis in patients at increased risk for mold infections.

Voriconazole's use as antifungal prophylaxis in patients with cancer at increased risk for mold infections is not well supported by clinical data despite its established use in the treatment of invasive aspergillosis.[57],[58] Side effects (most notably hepatotoxicity, rash, and phototoxicity) and the increased potential (relative to other azoles and the echinocandins) for drug interactions with voriconazole may limit its prophylactic use to patients at highest risk for mold infections. Similar to IV posaconazole, the use of IV voriconazole should be avoided in patients with significant renal impairment because of the potential toxicity of the vehicle. Oral voriconazole should be administered either 1 hour before or after a meal to optimize its absorption.

Posaconazole has demonstrated improved survival, a reduction in proven or probable IFI, and a reduction in invasive aspergillosis when compared with standard prophylaxis (either itraconazole or fluconazole) for the prevention of fungal infection in patients undergoing chemotherapy for AML or MDS.[59] Posaconazole was also effective prophylaxis in allogeneic HSCT recipients undergoing therapy for GVHD.[60] Posaconazole is currently available in both oral (solution and tablet) and parenteral (IV) formulations. The oral solution has been largely replaced by the tablet formulation because of its improved bioavailability and reduced dependency on the need

for coadministration with high-fat meals for optimal absorption.[61,62] Absorption of oral posaconazole may be reduced in patients with mucositis and in patients receiving acid-suppressing therapy.[63] In addition, the use of IV posaconazole is not recommended in patients with significant renal impairment because of the potential toxicity of the vehicle, betadex sulfobutyl ether sodium (SBECD).

Echinocandins

The echinocandins (eg, caspofungin, micafungin, and anidulafungin) may be useful as a prophylactic strategy in high-risk patients. Micafungin has been compared with fluconazole in autologous and allogeneic HSCT recipients.[31] Based on a composite endpoint (which included absence of breakthrough fungal infection and absence of empiric modifications to the antifungal regimen owing to neutropenic fever), micafungin was found to be superior. Although breakthrough candidemia, survival, and adverse events were similar in both groups, a trend toward a reduction in invasive aspergillosis in the allogeneic HSCT population was noted in the micafungin group. Micafungin is currently U.S. Food and Drug Administration (FDA) approved for the prevention of *Candida* infections in HSCT patients.

DURATION OF PROPHYLACTIC ANTIFUNGALS

Prophylaxis is generally continued during the period of neutropenia. In those with acute leukemia, MDS, or in autologous HSCT recipients, prophylaxis should continue until day 75 after transplant or through induction therapy for patients with leukemia.[64] Patients with a history of documented *Aspergillus* infection undergoing intensive chemotherapy should be considered for voriconazole.[8] Although the addition of a second prophylaxis (eg, echinocandin) may be considered, the benefits of combination therapy for secondary prophylaxis are unknown. Those patients with GVHD should continue prophylaxis until GVHD-related symptoms resolve.

NONABSORBABLE ANTIBACTERIALS

Because the GI tract is an important reservoir of potential pathogens, gut decontamination has been investigated.[15] However, the use of nonabsorbable antibacterial agents has been replaced by oral, absorbable antibiotics.[27]

ABSORBABLE (SYSTEMIC) ANTIBACTERIALS

The use of antibiotic prophylaxis is recommended for patients who are at high risk for febrile neutropenia or profound, protracted neutropenia (eg, AML/MDS), or HSCT treated with myeloablative conditioning regimens. Antibiotic prophylaxis is not routinely recommended for patients with solid tumors.

Trimethoprim–sulfamethoxazole

Although trimethoprim–sulfamethoxazole (TMP-SMX) decreases bacterial infections in patients with neutropenia,[65],[66] it may not reduce mortality in this patient population. The potential benefits of TMP-SMX prophylaxis must be carefully balanced against the potential for drug-induced bone marrow suppression, hypersensitivity reactions, hyperkalemia, nephrotoxicity, pancreatitis, the emergence of resistant organisms (eg, *E. coli*), and the development of superinfections. In addition, patients with leukemia receiving mucotoxic chemotherapy and TMP-SMX prophylaxis may be at increased risk for infections caused by viridans streptococci.[67],[68] However, TMP-SMX prevents PJP in patient populations with ALL and in those undergoing HSCT. Patients with malignancy at highest risk for experiencing PJP (ie, patients with ALL receiving intensive chemotherapy), allogeneic HSCT recipients, and those receiving alemtuzumab or phosphoinositide 3-kinase inhibitors (eg, alpelisib, idelalisib, copanlisib, and duvelisib) with or without rituximab or prolonged/high-dose corticosteroids (>20 mg of prednisone or its equivalent daily for ≥4 weeks) or temozolomide with radiation therapy should receive TMP-SMX prophylaxis.[8] Recipients of T-cell–depleting agents (eg, fludarabine or cladribine) and autologous HSCT recipients should also be considered for prophylaxis with TMP-SMX. In such settings, primary prevention should be continued

for up to 6 months (in the case of HSCT recipients) or longer (in cases in which immunosuppression is continued). In the setting of alemtuzumab therapy, such prophylaxis would generally continue for at least 2 months and until the CD4 count exceeded 200 cells/μL.[3] In patients requiring PJP prophylaxis but unable to tolerate TMP-SMX, patients should receive alternate prophylaxis with either atovaquone, dapsone, or pentamidine (either IV or via aerosol).[8] TMP-SMX is a preferred therapy for the prevention of PJP; however, it may be considered for use as primary prophylaxis for other typical microorganisms when unable to use a fluoroquinolone.

Fluoroquinolones

The fluoroquinolones ciprofloxacin and levofloxacin are used by some centers as prophylaxis for adult patients at high risk for infection.[69],[70] Of concern, however, is the increasing frequency of gram-positive infections (including viridans streptococci) and resistant gram-negative bacilli (most notable in *P. aeruginosa* and *E. coli*)[71] in patients receiving fluoroquinolone prophylaxis.[67],[68],[72],[73] Meta-analyses report reductions in mortality in high-risk patients receiving prophylaxis with these fluoroquinolones.[69],[74] Because fluoroquinolone prophylaxis is offset by the emergence of resistant organisms, routine prophylactic use in low-risk patients should generally be avoided.[27] However, those at intermediate or high-risk for bacterial infections (ie, those patients with an ANC ≤100 neutrophils/μL for >7 days) should be considered for fluoroquinolone prophylaxis until either the onset of fever (at which time empiric antibacterials would be started) or resolution of severe neutropenia.[27] Levofloxacin is preferred over ciprofloxacin in patients with or at increased risk for oral mucositis–related infection because of the potential of invasive viridans streptococci.[4] Regardless of the fluoroquinolone chosen, local resistance patterns should be closely monitored before such prophylaxis is chosen.

Penicillin

Because of the increased risk of invasive pneumococcal infections, select patient populations (notably patients with asplenia, allogeneic HSCT recipients [owing to functional asplenia and impaired B-cell immunity], and those undergoing immunosuppression for GVHD) should be considered for prophylaxis with penicillin. In patients with chronic GVHD, penicillin prophylaxis may be continued during the administration of immunosuppressive agents. In HSCT recipients, prophylaxis should begin 3 months after transplant and continue for 1 year after transplant. Alternative prophylaxis (eg, TMP-SMX) should be considered in areas where penicillin resistance in pneumococci is significant.

ANTIVIRALS

Most HSV disease in patients with cancer is a consequence of reactivation from latent infection. High-risk patients (eg, seropositive for HSV undergoing allogeneic HSCT or induction or reinduction therapy for acute leukemia, or has GVHD requiring steroid treatment, or a patient receiving alemtuzumab therapy) or intermediate-risk patients (eg, seropositive for HSV and undergoing autologous HSCT; or a patient with lymphoma, multiple myeloma, and CLL; or receiving purine analog therapy [eg, fludarabine]); or low-risk patients previously requiring treatment for HSV reactivation should be given antiviral prophylaxis. Both oral or IV acyclovir and oral valacyclovir are appropriate initial choices in most patients. Published data for famciclovir for this indication are lacking. Those receiving foscarnet or ganciclovir (most commonly for prevention and treatment of CMV infection) do not require additional prophylaxis for HSV, given the activity of these against Herpes simplex. Prophylaxis should be administered during periods of neutropenia, and for at least 1 month after HSCT.[27] The duration may be extended in those undergoing allogeneic HSCT with GVHD. Patients receiving alemtuzumab may also require extended prophylaxis of up to 2 months after completion of therapy or recovery of $CD4^+$ cell counts >200 cells/μL, whichever is later.

Similar to HSV, VZV in patients with cancer is most commonly reactivation. HSCT patients who are seropositive for VZV should also be given long-term prophylaxis (6–12 months for autologous HSCT and at least 1 year for allogeneic HSCT), particularly with receipt of either bortezomib or alemtuzumab. Extending prophylaxis in allogeneic HSCT patients should be considered in the setting of continued immunosuppressive therapy. As with HSV, patients receiving alemtuzumab may also require extended prophylaxis of up to 2 months after completion of therapy or recovery of $CD4^+$ cell counts >200 cells/μL, whichever is later. Patients receiving proteasome inhibitors (eg, bortezomib, carfilzomib, ixazomib) should also receive VZV prophylaxis during active therapy including periods of neutropenia. Agents active against HSV are also useful for VZV prevention. In one study, low-dose (ie, 500 mg/day three times weekly) valacyclovir prophylaxis after a 35-day course of IV acyclovir is safe and effective in allogeneic HSCT recipients.[75]

CMV infections frequently occur in patients with cancer who undergo allogeneic HSCT or who receive alemtuzumab. Infection may result from reactivation (immunocompromised, CMV-seropositive individuals) or primary infection (CMV-seronegative individuals). The highest risk of CMV reactivation occurs in individuals undergoing allogeneic HSCT who are CMV seropositive before transplant. Allogeneic HSCT recipients should undergo a surveillance period (typically for at least 1–6 months after transplant in donor or recipient CMV IgG seropositive cases or GVHD requiring therapy) and should be considered for primary antiviral prophylaxis with letermovir. CMV surveillance consists of weekly monitoring by polymerase chain reaction (PCR). CMV surveillance is also recommended for individuals receiving alemtuzumab for a minimum of 2 months after therapy. Preemptive CMV therapy (administration of antiviral agents to asymptomatic patients with laboratory markers of viremia to prevent CMV disease) is recommended in high-risk individuals for at least 2 weeks and until CMV is no longer detected. Preferred preemptive therapy includes valganciclovir (orally [PO]) or ganciclovir (IV). Foscarnet (IV) or cidofovir (IV) are generally reserved as second-line agents for preemptive therapy (such as in

the setting of ganciclovir-resistant CMV or neutropenia secondary to ganciclovir).[76–80] Letermovir is not indicated for preemptive therapy or treatment of CMV. Furthermore, letermovir does not have activity against other herpes group viruses (HSV or VZV). Therefore, acyclovir is also needed in such patients. Maribavir is a new antiviral agent currently approved for solid organ transplant recipients with CMV infection refractory to ganciclovir/valganciclovir, foscarnet, and cidofovir. It lacks activity against HSV, VZV, or HHV-6.

Patients with prior infections with HBV or hepatitis C virus (HCV) can experience reactivation of infection secondary to immunosuppressive therapy. Reactivation of infection can occur in patients infected with HBV undergoing immunosuppressive therapy (most notably in allogeneic HSCT recipients or those receiving B-cell depleting therapy). Therefore, serologic screening (utilizing testing for hepatitis B surface antigen [HBsAg] and hepatitis B core antibody [HBcAb]) is generally performed in patients at increased risk for infection. Prophylaxis should be considered in patients with positive test results. Patients with one or more of these screening test results that are positive often undergo further testing for active viral replication (utilizing a quantitative PCR test for HBV DNA). Preemptive therapy should be considered in patients with evidence of viral replication. Entecavir and tenofovir are considered preferred options and have largely replaced lamivudine monotherapy in such settings because of the high incidence of viral resistance.

Respiratory tract infections caused by RSV, influenza, and parainfluenza are less commonly observed in patients with neutropenia. Although response to influenza virus vaccine may be attenuated, patients undergoing cancer treatment should receive annual vaccinations with inactivated influenza vaccine. Whenever possible, the timing of such vaccinations may be best between cycles (>7 days after or >2 weeks before the next treatment). In contrast, immunocompromised patients should not receive the intranasal live virus vaccine.

Hematopoietic Growth Factors

Hematopoietic colony-stimulating factors (CSFs) such as granulocyte colony-stimulating factor (G-CSF; filgrastim or tbo-filgrastim), pegylated G-CSF (pegfilgrastim), or granulocyte-macrophage colony-stimulating factor (GM-CSF; sargramostim) are important adjuncts in patients with cancer.[81] Since 2009, several biosimilar G-CSFs have been approved (eg, filgrastim-sndz, filgrastim-aafi, pegfilgrastim-jmdb, pegfilgrastim-cbqv, and pegfilgrastim-bmez). Studies in patients with cancer receiving myelosuppressive or myeloablative chemotherapy have demonstrated that concurrent prophylactic use of the CSFs can reduce the incidence, duration, and severity of neutropenia.

Risk factors for neutropenia include age (ie, older than 65 years), medical history (including prior history of febrile neutropenic episodes, nutritional status, unstable comorbidities, and presence of active infections), disease characteristics (especially those involving the bone marrow resulting in cytopenias), and myelotoxicity of the regimen (including both chemotherapy and radiation) used to treat the underlying malignancy.[9],[28],[81] Many studies have shown that the prophylactic use of hematopoietic growth factors (more specifically G-CSF) reduces the incidence of chemotherapy-induced febrile neutropenia.[9],[28],[81] However, routine use of CSFs for the prevention of febrile neutropenia is discouraged in patients at low risk (<10%) for febrile neutropenia. Use as primary prophylaxis in patients at high risk (>20%) for fever and neutropenia is recommended. In addition, some guidelines also recommend the administration of CSFs for primary prevention for patients 65 years or older with diffuse aggressive lymphoma treated with curative chemotherapy (especially in the setting of significant comorbidities and in those receiving select dose-dense chemotherapy regimens). Although the benefits of CSFs are less clear in patients at intermediate risk (10%–20% risk of febrile neutropenia), they should be considered on a case-by-case basis. CSFs are generally avoided as prophylaxis in patients undergoing radiation therapy concomitant with chemotherapy because of the potential for thrombocytopenia[82] or reductions in tumor response.[83] Administration is generally continued 3 to 4 days after chemotherapy administration and continued until a

sufficient and stable post-nadir ANC recovery is established. Pegylated G-CSF may be preferred in some settings owing to the convenience of single administration.[28,84]

Consideration of the use of CSFs as secondary prophylaxis (ie, prevention of febrile neutropenia in patients undergoing second or subsequent cycles of chemotherapy) should be based on repeated assessments of patient risk of febrile neutropenia. Patients experiencing prior episodes of febrile neutropenia or neutropenia limiting the dose of chemotherapy without prior CSFs should be considered for secondary prophylaxis.

Other Agents

Although beyond the scope of this chapter, select vaccinations have also been recommended for both autologous and allogeneic HSCT recipients (primarily caused by a decline in antibody titers to many vaccine-preventable diseases).[8] These include (but are not limited to) administration of pneumococcal, influenza virus, and *H. influenzae* vaccines. Live vaccinations should be avoided in this population. However, because immune response may be altered immediately after transplant, delays of up to 3 months after cessation of immunosuppressive chemotherapy is recommended for many vaccines. This is most notable in patients receiving consolidation therapy for acute leukemia. Data regarding the safe use of vaccines in patients with cancer receiving immunostimulants are sparse. In addition, serologic testing of antibody response is recommended in selected settings.[8]

Although data to support use are limited, intravenous immunoglobulins (IVIGs) have been recommended for HSCT recipients with severe hypogammaglobulinemia (ie, serum IgG level <400 mg/dL) and recurrent infections.[8] IVIGs have been used as adjuncts in the prevention and treatment of CMV infections. In contrast, granulocyte transfusions have not been proved to be effective in either prevention or treatment of infection in the neutropenic cancer patient.[85]

INFECTIONS IN NEUTROPENIC CANCER PATIENTS

Clinical Signs and Symptoms

Case 75-1, Question 4: Seven days after completing chemotherapy, B.C. experienced a fever of 102 °F (38.9 °C; orally). Vital signs are blood pressure, 109/70 mm Hg; pulse, 102 beats/minute; and respirations, 25 breaths/minute. Physical examination demonstrates a clear oropharynx without exudates or plaques. Chest and cardiac examinations are normal. The exit site for the Hickman catheter is clean and nontender without signs of erythema or induration. The perineum and rectum are nontender, and no masses are noted. Laboratory data are as follows:

Hematocrit, 20%
Hemoglobin, 7 g/dL
WBC count, 1400 cells/μL, with 3% PMNs, 1% band forms, 70% lymphocytes, and 22% monocytes
Platelet count, 17,000 cells/L
Blood glucose, 160 mg/dL
Serum creatinine (SCr), 1.1 mg/dL
Blood urea nitrogen (BUN), 24 mg/dL

What are the signs and symptoms of infection in B.C.? What are the most common sites and sources of infection in patients such as B.C.?

B.C. has an ANC of 48 cells/μL (1400 WBCs/μL × [0.03 PMNs + 0.01 bands]) and is therefore at high risk for infection.

Fever in patients with neutropenia is defined as a single oral temperature of at least 101 °F (38.3 °C) or an oral temperature of at least 100.4 °F (38.0 °C) for >1 hour in the absence of an obvious cause.[4] It is the earliest (and often the only) sign of infection in patients with neutropenia, because typical signs can be modified or absent in this patient population. However, only 50% to 60% of patients with febrile neutropenia have occult or documented infections. Noninfectious sources of fever in the neutropenic cancer patient include inflammation, tumor progression, tumor lysis, adverse drug reactions, and transfusion reactions.[2,86] Signs and symptoms

consistent with a diagnosis of infection without fever should be considered to be infection in the neutropenic host until proved otherwise.

In patients with documented infections, the most common sites are skin, mouth, throat, esophagus, sinuses, abdomen, rectum, liver, vascular access, lungs, and urinary tract.[87] Although the lung is the most common site of serious infection in neutropenic cancer patients, fever and dry cough are often the only presenting signs of pneumonia.[87] The impaired inflammatory response results in scant sputum production, and sputum Gram stains often contain few PMNs. Radiologic evidence of a pulmonary infection can be minimal or absent, and the chest examination is frequently not diagnostic.[88] Pneumonia is associated with high mortality in patients with neutropenia, particularly in the setting of bacteremia. In the presence of shock, a mortality rate of ~80% has been observed in these patients.[89]

Invasive procedures such as venipuncture, central IV catheter placement (eg, Hickman catheter), and skin biopsies are associated with cellulitis and systemic infections. However, the typical signs and symptoms of infection (eg, pain, heat, erythema, and swelling) are often absent in part owing to inadequate granulocytes.[87] Colonization of these lesions may result in local infection and the potential for systemic dissemination of bacteria and fungi. Bacteremia occurs primarily from entry of bacteria through the skin or through unrecognized ulcerations in the GI and perirectal areas.

Confirmation of Infection

Case 75-1, Question 5: How can a suspected infection be confirmed in patients such as B.C.?

Because of the frequent lack of “typical” physical signs and symptoms of infection, an accurate history (including the cancer type and treatment regimen, new signs of infection, antimicrobial prophylaxis, prior infections, and comorbidities) should be obtained

and a thorough physical examination performed at the first sign of fever. Further procedures generally depend on the level of infection risk and its complications (low vs high risk [refer to section on Initial Empiric Antibiotic Selection for details]). A detailed search for subtle signs and symptoms of inflammation at the most common sites, such as the oropharynx, bone marrow aspiration sites, lung, periodontium, skin, vascular catheter access sites, nail beds, and perineum (including the anus) is necessary. Before antibiotics are initiated, two sets of blood cultures (with each set consisting of two culture bottles) should be obtained if possible, but should not delay the start of antibiotics if the patient is clinically unstable.[2,4] In patients with indwelling central venous catheters, one of the two sets of blood cultures should be obtained from the catheter to help rule out catheter-related infection.[4] Diarrheal stools may be tested for the presence of *C. difficile*. Additional Gram stain and cultures (eg, stool, urine, skin, IV site, respiratory specimens) should be obtained depending on signs and symptoms. The yield from such cultures, however, may be affected by the prior or concurrent administration of prophylaxis.[3] Chest radiographs and oximetry should be obtained in the presence of respiratory symptoms.[4] Respiratory virus testing should take place for patients with upper respiratory tract infection symptoms (ie, coryza) or cough.[4] In settings in which pulmonary aspergillosis is suspected, further radiologic evaluations (such as computed tomography scans) should be considered.[25] A complete blood count, comprehensive metabolic panel, coagulation, C-reactive protein, urinalysis, and assessment of organ function (eg, liver and kidney function) should be obtained to assist in drug dosing and to establish baseline values to monitor for treatment-related toxicities.[2]

Recent advances have been made in nonculture-based diagnostic tests that help support (or, in some cases, eliminate) the diagnosis of infection in these patients.[90] Such biomarkers include C-reactive protein[91–93] and procalcitonin.[93–95] However, these tests are not routinely ordered, and their role in the treatment of the neutropenic cancer patient has not yet been established.[2] Galactomannan

(specific for aspergillosis)[96] and β-D-glucan testing may assist in the diagnosis of fungal infections.[97],[98] Serial galactomannan testing has also been used preemptively to initiate antifungal therapy before overt signs and symptoms of IFIs occur.[99] In addition to other issues regarding sensitivity and specificity of these assays, both galactomannan and β-D-glucan are affected by prior or current receipt of antifungals.[25] At present, the use of these tests should be restricted to persistent fever despite other etiologic investigations.[4]

Significance of Colonization

Case 75-1, Question 6: Routine surveillance cultures of swabs taken from B.C.'s axillae, nasopharynx, and rectum grew *Corynebacterium jeikeium* (axillae), *S. aureus* (axillae and nasopharynx), and *Enterococcus faecium* (rectum). What is the significance of these culture results? Should routine, serial surveillance cultures be performed in patients such as B.C.?

Several factors influence the colonization and subsequent infection by microorganisms in patients with cancer. Organisms isolated from infected patients can be found in endogenous flora or acquired during hospitalization. Factors leading to colonization include staff-to-staff and patient-to-patient transmission (eg, lack of frequent and adequate hand hygiene), direct transmission from the environment (eg, inadequately disinfected bathtubs, sinks, toilet bowls), foods (eg, raw fruits and vegetables), inhalation from contaminated fomites (eg, respirators, ventilating systems), and IV access devices. In addition to immunosuppression, the underlying malignancy and associated chemotherapy diminish the resistance of the patient with cancer to colonization and infection.

The acquisition of and subsequent colonization by potentially pathogenic microbes may be detected by serial surveillance cultures of specimens obtained from various body sites such as the nasopharynx, axilla, and rectum, besides from urine. Such surveillance cultures may be useful for infection control purposes. However, little clinically useful information is gained in the absence

of infection. Therefore, routine use of surveillance cultures is generally restricted to select patients for infection control purposes. In such cases, culture of the anterior nares (for MRSA) or rectal samples (for VRE or multidrug-resistant gram-negative bacilli) may be performed.

In summary, B.C.'s surveillance culture results indicate that she is colonized with several potential pathogens associated with infection in the immunocompromised host, but these results are probably not useful in selecting empiric antibiotics for her fever.

EMPIRIC ANTIBIOTIC THERAPY

Rationale

Case 75-1, Question 7: Should B.C. be started on antibiotic therapy immediately considering that neither the source of her fever nor the pathogen has been established?

Neutropenic cancer patients with fever and/or other signs and symptoms of infection should undergo prompt risk assessment and initiation of antibiotic therapy. Once culture results are obtained, these patients should be emergently started on broad-spectrum antibacterials (within 1 hour of triage). Prompt institution should not be delayed if culture results cannot be obtained. Early studies confirmed high mortality in patients with neutropenia with untreated gram-negative infections up to 24 to 48 hours after the onset of fever. Crude mortality rates secondary to *P. aeruginosa* bacteremia approached 91%.[6] Prompt use of empiric, broad-spectrum antibiotics has resulted in significant reductions in infectious mortality rates.

Initial Empiric Antibiotic Regimens

Case 75-1, Question 8: What pathogen- and patient-specific factors should be considered when initiating empiric therapy for B.C.?

Consensus guidelines prepared by the Infectious Diseases Society of America[2,4] and the European Society of Medical Oncology[1] identify antimicrobial options for the treatment of fever in the neutropenic cancer patient. The ideal antibiotic regimen for empiric management in this setting (ie, those without evidence of site- or pathogen-specific infections) remains controversial. Determination of patient risk of infection aids in determining the site of care and (therefore) the therapeutic options for management. High-risk patients are those with an MASCC Risk Index score <21 or a clinical index of stable febrile neutropenia (CISNE) score ≥3, inpatient status at the time of development of fever, significant medical comorbidity or clinically unstable, allogeneic HSCT, anticipated prolonged severe neutropenia, hepatic insufficiency, renal insufficiency, uncontrolled/progressive cancer, pneumonia or other complex infections at clinical presentation, receiving alemtuzumab, or mucositis grades 3 to 4. These patients generally receive IV therapy in a hospitalized setting. In contrast, low-risk patients are generally characterized by outpatient status at time of development of fever, no associated acute comorbid illness, anticipated short duration of severe neutropenia, good performance status (Eastern Cooperative Oncology Group [ECOG] 0–1), no hepatic or renal insufficiency, an MASCC Risk-Index Score of ≥21 or a CISNE score of <3) and may be candidates for oral therapy at home or in alternate care settings (such as an ambulatory clinic).

In addition to the assessment of a patient's risk factor for infection, selecting an initial empiric regimen for a given patient should take into account likely pathogens, infection site–specific antibiotic efficacy, and institutional susceptibility patterns. This point is especially true in areas experiencing a growing frequency of multidrug-resistant organisms, such as MRSA, VRE, and extended-spectrum β-lactamase (ESBL)-producing organisms (such as *K. pneumoniae* and *E. coli*).[100] Additional patient-related considerations

should include allergies and prior and concomitant antimicrobials. Finally, dosing schedules, acquisition costs, and the potential for significant toxicities should be considered. In addition to broad-spectrum activity, antibacterial regimens should be bactericidal against the infecting pathogen. However, no adequately controlled comparative trials of bacteriostatic versus bactericidal antibiotics have been conducted in humans.

Optimal Antibacterial Spectrum

Case 75-1, Question 9: Given the lack of site-specific signs and symptoms of infection, what would be a reasonable initial empiric antibiotic regimen for B.C.?

Despite continued development in antibacterial drugs, the empiric management of patients with febrile neutropenia is complicated by the changing spectrum of bacterial pathogens and their antimicrobial susceptibilities. Empiric antibiotic regimens should provide broad-spectrum coverage against the potential gram-negative bacilli most commonly isolated from neutropenic cancer patients (eg, *E. coli, K. pneumoniae, P. aeruginosa*), staphylococci, and viridans streptococci. Because mortality from untreated bacteremia caused by *P. aeruginosa* is so high,[6] empiric regimens have traditionally included antimicrobials with antipseudomonal activity.

In summary, many organisms, including those recovered from surveillance cultures, may be pathogens in B.C. Those associated with a high mortality rate during the first 48 hours should be empirically treated pending culture and sensitivity results. Therefore, an empiric regimen with optimal activity against commonly isolated gram-negative bacilli (including *P. aeruginosa*) should be promptly administered to B.C.

ORAL ANTIBIOTICS

Carefully selected (ie, low risk) adult patients with febrile neutropenia may be candidates for oral antibiotic therapy, either as initial therapy

or as follow-up to IV antibiotics (sequential therapy).[1,2,101–103] Patients must be able to tolerate oral medications. In general, patients considered for oral therapy must be without microbiologic or clinical evidence of infection (other than fever), clinically stable, and closely observed. Patients with severe (ANC <100 cells/μL), or lasting anticipated >7 days, or those receiving prior fluoroquinolone prophylaxis would not be eligible. This would also exclude patients with any of the following: serious comorbidities, inpatient acquisition of infection, uncontrolled malignancy, pneumonia, recent HSCT, dehydration, hypotension, chronic lung disease, abnormal liver (more than three times the upper limit of normal) or renal function (SCr >2 mg/dL), or signs and symptoms lasting >7 days.[2] An international collaborative study established and validated a risk scoring system in adults that incorporated these principles to identify low-risk patients for whom oral therapy may be an option.[29]

Cefixime has been used effectively as an alternative regimen in low-risk pediatric patients initially receiving IV therapy,[104] but there is not adequate experience to recommend it at this time. It also lacks activity against *Pseudomonas*. Fluoroquinolone-containing regimens have been the mainstay of most oral regimens used in this setting. Patients already receiving fluoroquinolones as prophylaxis should be excluded from receiving this regimen. Oral ciprofloxacin (500–750 mg every 12 hours) in combination with amoxicillin–clavulanate (875 mg administered every 12 hours) is useful in low-risk adult patients with febrile neutropenia[105,106] and is the most commonly used oral regimen.[2] Oral levofloxacin may be used in place of ciprofloxacin, and oral clindamycin may be used in place of amoxicillin–clavulanate if the patient is allergic to β-lactam antibiotics. More recently, moxifloxacin has been evaluated in this patient population and demonstrates efficacy comparable to combination regimens containing ciprofloxacin.[107,108] Both levofloxacin and moxifloxacin demonstrate superior activity in vitro when compared to ciprofloxacin against *S. pneumoniae.* Although moxifloxacin permits simplification of the regimen, it lacks activity against *Pseudomonas.* Therefore, levofloxacin is generally the preferred fluoroquinolone in such

settings. Moxifloxacin use should be restricted to patients at low risk for pseudomonal infections.

Low-risk patients with adequate home support (eg, access to emergency facilities, phone access) and the desire for home treatment may be treated as outpatients (with either IV or oral therapy). Therapy is usually initiated in a clinic or hospital setting.[2] Monitoring in the outpatient setting should include either home nursing or office visits daily for 3 days to review progress and to screen for problems. Patients who are stable and responding after the initial observation period may continue to receive monitoring by phone contact.

Continued administration of antimicrobials in the outpatient setting initiated as an inpatient has been suggested in a subset of low-risk patients. The criteria used to define eligibility for outpatient therapy are generally similar to those established and previously discussed for oral therapy. Therefore, continued outpatient administration of parenteral antibiotics can be considered in a subset of low-risk patients with close medical follow-up.[2]

INTRAVENOUS MONOTHERAPY

High-risk patients requiring IV therapy are often candidates for monotherapy regimens, including an antipseudomonal β-lactam such as a fourth-generation cephalosporin (eg, cefepime), or a carbapenem (eg, imipenem–cilastatin or meropenem).[2] Initial, empiric use of additional antibiotics (eg, fluoroquinolones, aminoglycosides, and vancomycin) may be added for patients who are clinically unstable.[2] For patients with severe β-lactam allergies, the use of vancomycin plus aztreonam may be considered. Alternative initial empiric parenteral regimens (excluding those containing vancomycin) have been investigated in this patient population.[1,2,4,86] However, because no significant differences exist among any of these empiric approaches, monotherapy is employed and recommended in most patients. There are no convincing data to support one choice over the others as empiric monotherapy.

Antipseudomonal cephalosporins

Although ceftazidime monotherapy has been found to be as effective as is combination therapy, its efficacy as monotherapy in patients with documented staphylococcal and streptococcal infections was suboptimal. Select clinical trials have empirically added antistaphylococcal coverage with a glycopeptide (eg, vancomycin) and have shown improved outcomes in these patients. In addition, pathogens (particularly gram-negative pathogens) that produce either type 1 β-lactamase or ESBL (eg, *K. pneumoniae*) are not likely to respond to ceftazidime monotherapy. These organisms are more likely with prolonged hospitalization or receipt of antimicrobial therapy. Local in vitro susceptibilities of common gram-negative pathogens should be examined before the routine use of ceftazidime as monotherapy. Therefore, despite extensive experience for use as empiric treatment of fever in patients with neutropenia, concerns with weak gram-positive coverage and breakthrough infections limit its utility and therefore is no longer generally considered a preferred monotherapy agent given the availability of alternate effective and well-tolerated monotherapy options.[2]

Cefepime is a fourth-generation cephalosporin with an FDA-approved indication for monotherapy for empiric management of infection in patients with febrile neutropenia. The potential advantage of this agent compared with third-generation cephalosporins is its low affinity for major chromosomally mediated β-lactamases. Compared with ceftazidime, cefepime has more potent activity in vitro against select gram-positive bacteria (methicillin-susceptible *Staphylococcus* species, viridans streptococci, and *S. pneumonia*e). Similar to ceftazidime, numerous randomized, comparative studies have evaluated the role of cefepime as monotherapy in both adults and children with febrile neutropenia. The improved gram-positive activity (relative to ceftazidime) may decrease the empiric need for vancomycin in some patients. However, this advantage is less likely in institutions with a high rate of MRSA because cefepime and other cephalosporins (with the exception of ceftaroline) are inactive against this pathogen. Although a meta-analysis published in 2007

suggested increased all-cause mortality in patients with neutropenia treated empirically with cefepime,[109],[110] subsequent analysis by the FDA concluded that no such differences existed when compared with control patients.

Carbapenems

The carbapenems are a unique class of antibiotics with broad-spectrum activity against numerous gram-positive and gram-negative bacteria, including anaerobes. In addition, carbapenems may be used in the setting in which the patient is at increased risk for ESBL-producing gram-negative pathogens (such as *K. pneumoniae* or *E. coli*). Agents with increased anaerobic activity (including carbapenems) might be used as empiric therapy in cases in which an intra-abdominal infection is suspected. Imipenem (in combination with the dehydropeptidase inhibitor cilastatin) and meropenem are two currently available agents in this class that have been studied as monotherapy for patients with febrile neutropenia.

Clinical outcomes with imipenem–cilastatin monotherapy have been comparable with those of the β-lactam plus aminoglycoside combinations. Although effective, imipenem–cilastatin has generally been associated with a higher incidence of nausea and vomiting compared with ceftazidime or meropenem.[111],[112] The GI side effects are generally dose related (3–4 g/day) and associated with the rate of IV administration. Therefore, dosages of 2 g/day (divided every 6 hours) are generally given to patients with normal renal function.

Meropenem monotherapy for febrile neutropenia has been evaluated in both adults and children, and the results have supported the value of meropenem as empiric monotherapy for use in patients with febrile neutropenia. Meropenem may have advantages over imipenem–cilastatin in the treatment of central nervous system infections (owing to less associated seizure activity).

Although ertapenem possesses microbiologic activity comparable to that of the other carbapenems, it lacks in vitro activity against *Acinetobacter* species and *Pseudomonas,* including *P. aeruginosa.*

Therefore, ertapenem would not be appropriate as empiric therapy for patients with febrile neutropenia.

Routine carbapenem use may be associated with increased drug acquisition cost (relative to cephalosporins) and increased potential for the development of carbapenem resistance. Therefore, many institutions have elected to reserve the carbapenems for patients who have failed to respond to prior empiric therapy, have a history of infections with pathogens resistant to fourth-generation cephalosporins, are clinically unstable, or have need for expanded anaerobic coverage.

β-Lactam/β-lactamase inhibitors

Randomized trials have compared piperacillin–tazobactam monotherapy to various antibiotics. Published trials have documented that piperacillin–tazobactam is not inferior to cefepime in this patient population.[113],[114] Although experience with this agent as monotherapy is limited relative to that for the antipseudomonal carbapenems and antipseudomonal cephalosporins, it is considered to be an adequate choice for monotherapy.[2] Higher doses of piperacillin–tazobactam (ie, 3.375 g IV every 4 hours or 4.5 g IV every 6 hours in adult patients with normal renal function) should be used because of the risk of pseudomonal infections. More recently, many institutions utilize an extended-infusion protocol for the administration of piperacillin–tazobactam (ie, 4.5 g IV infused over 3–4 hours every 8 hours) to maximize its time-dependent effects. Piperacillin–tazobactam may interfere with the galactomannan assay used in the diagnosis of select IFIs, including aspergillosis.

INITIAL ANTIBACTERIAL COMBINATIONS (EXCLUDING VANCOMYCIN)

CASE 75-2

QUESTION 1: B.L., a 13-year-old male, presented with a 3-week history of "always being tired" and a persistent sore throat. Initial evaluation revealed anemia, thrombocytopenia, and a WBC count of 130,000 cells/L, with a

predominance of immature lymphoblasts. Further evaluation demonstrated that B.L. had high-risk ALL. Remission induction treatment was initiated with teniposide plus cytarabine followed by prednisone, vincristine, and L-asparaginase. Seven days after induction chemotherapy, B.L. experienced a fever of 102 °F (38.89 °C) and chills. The ANC was 48 cells/μL. SCr and BUN were 1.0 and 15 mg/dL, respectively. The physician wants to empirically start B.L. on cefepime plus gentamicin combination regimen.

What is the role of this combination in the empiric management of febrile neutropenia? Are there any differences in efficacy between these combinations?

Before the introduction of third- and fourth-generation cephalosporins and carbapenems, the empiric use of antibacterial combinations in febrile neutropenic cancer patients was favored because these regimens offered a broader spectrum of activity against bacteria commonly infecting patients with cancer.[115] In addition, these combinations offered the potential for an expanded empiric coverage.[115],[116] However, infections in patients with neutropenia have shifted largely from gram-negative to gram-positive pathogens, for which these traditional combination regimens have limited efficacy. Despite this concern, some clinicians continue to favor antibiotic combinations as initial empiric therapy, especially in patients who are clinically unstable or at increased risk for multidrug-resistant pathogens. Until the 1980s, most patients with febrile neutropenia were treated with two-drug combination regimens that contained an aminoglycoside (gentamicin, tobramycin, or amikacin) plus a β-lactam antibiotic, such as antipseudomonal penicillin, or a third-generation cephalosporin. This combination is one of the most established empiric treatment regimens for the management of febrile neutropenia.

Numerous studies have been conducted to evaluate the efficacy of combination therapy of an aminoglycoside with an antipseudomonal cephalosporin (ceftazidime and cefepime). Antipseudomonal penicillins plus β-lactamase inhibitors (in combination with an aminoglycoside) would also be considered a comparable regimen. A better outcome was demonstrated with full-course amikacin plus ceftazidime than with a short course (3 days) of amikacin plus a full

course of ceftazidime.[117] However, the longer course of the aminoglycoside is likely to be associated with more toxicity.

Because carbapenem antibiotics are more frequently evaluated as monotherapy in this patient population, there are limited studies examining the combination of an aminoglycoside with either imipenem–cilastatin or meropenem. However, in one such evaluation, the combination of imipenem–cilastatin plus amikacin was found to be superior to imipenem–cilastatin monotherapy.[118] Carbapenems (in combination with aminoglycosides and vancomycin) have been recommended as empiric initial therapy for patients who are clinically unstable.

Aminoglycosides have generally been considered the backbone of combination regimens because of their potential for bactericidal action against various bacteria. However, the addition of an aminoglycoside is associated with increased costs for therapeutic monitoring. The benefit of an aminoglycoside for empiric therapy has not been consistently demonstrated.[118,119] In addition, there is an increased potential for the development of nephrotoxicity and ototoxicity.[119] This concern is especially relevant in patients receiving concomitant nephrotoxins (such as cisplatin and cyclosporine).

In summary, the use of initial empiric therapy with combination antibiotic therapy is generally reserved for patients who are clinically unstable (eg, hypotension, tachycardia, tachypnea, mental status changes). In such settings, IV therapy with an antipseudomonal β-lactam is generally combined with an aminoglycoside and vancomycin. Therefore, B.L. may be treated with IV cefepime monotherapy. The addition of an aminoglycoside may not have an additional benefit and may increase the risk of harm by causing significant adverse effects.

Case 75-2, Question 2: Seven days into therapy, despite rehydration, B.L.'s SCr and BUN rose to 2.0 g/dL and 45 mg/dL, respectively. Because B.L. has nephrotoxicity (believed to be secondary to the aminoglycoside), what other combination regimens (excluding those containing aminoglycosides) could be used? Are these regimens as effective as aminoglycoside-containing regimens?

As stated, ciprofloxacin has been studied in combination with other antibacterials (either an aminoglycoside or a β-lactam, including an antipseudomonal penicillin) as initial empiric therapy for the treatment of suspected infection in patients with febrile neutropenia.[120–123] Ciprofloxacin in combination with clindamycin may also be useful in patients unable to receive β-lactam–containing combinations owing to the presence of immediate-type hypersensitivity reactions.[4] These studies, however, were associated with increased gram-positive infections in patients treated with ciprofloxacin. In addition, the in vitro activity of ciprofloxacin against *P. aeruginosa* has declined significantly (to <70% in many institutions). Therefore, if used as part of combination therapy, ciprofloxacin should be combined with an antimicrobial with favorable in vitro activity against this pathogen. Alternatively, the combination of aztreonam and vancomycin has been recognized as reasonable empiric combination therapy in patients with immediate-type hypersensitivity reactions to penicillin.[4]

In summary, the use of initial empiric therapy with combination antibiotic therapy is generally reserved for patients who are clinically unstable. These patients may receive IV therapy with an antipseudomonal β-lactam generally combined with an aminoglycoside and vancomycin. Systemic antifungals (such as fluconazole or an echinocandin) may also be added in such settings, especially in patients not receiving antifungal prophylaxis. This is discussed further in the upcoming section on Antifungal Therapy.

EMPIRIC VANCOMYCIN

Case 75-2, Question 3: B.L. is started on a two-drug regimen of cefepime and vancomycin. What is the rationale for adding vancomycin to the regimen?

As discussed, gram-positive bacteria are important pathogens in these patients. Because cephalosporins lack activity against methicillin-resistant staphylococci, vancomycin is often added to empiric regimens. A growing proportion of *S. aureus* infections are

methicillin resistant (as many as 60% in some institutions). However, widespread use of vancomycin may be one factor associated with the rise in vancomycin resistance among enterococci. Furthermore, vancomycin intermediate–resistant *S. aureus* and rare case reports of *S. aureus* fully resistant to vancomycin have been reported. Vancomycin use has also been associated with a modest increase in the incidence of nephrotoxicity.

Primarily because of differences in the measured endpoints, the need for vancomycin as initial empiric therapy continues to be debated.[124] For example, patients with cancer with febrile neutropenia had more rapid resolution of fever, fewer days of bacteremia, and a lower frequency of treatment failure when vancomycin was added to an initial regimen of antipseudomonal penicillin plus an aminoglycoside.[125],[126] Similarly, the addition of vancomycin to ceftazidime showed improved results compared with ceftazidime alone or with a three-drug combination.[127] However, other studies have concluded that mortality was not increased when vancomycin therapy was delayed.[128–131] The mortality from staphylococcal (generally coagulase-negative staphylococci) infections is generally considered to be low (<4%) during the first 48 hours after the onset of fever. In contrast, the mortality associated with viridans streptococcal infections is higher among patients who are not initially treated with vancomycin.[132] Some strains of viridans streptococci are either resistant or tolerant to penicillin.[132],[133] In general, vancomycin would represent a reasonable alternative treatment of such infections or in patients allergic to penicillins.

There continues to be considerable debate about whether vancomycin should be included in the initial empiric regimen for patients with febrile neutropenia.[124] In general, routine use of empiric vancomycin should be discouraged.[2] However, for institutions frequently isolating invasive gram-positive bacterial pathogens (eg, those caused by viridans streptococci), vancomycin should probably be included in the initial empiric regimen. In addition, patients at highest risk of serious, invasive infections with gram-positive organisms should be considered for initial vancomycin therapy. Such patients include suspected catheter-related infections, skin or soft

tissue infections, or pneumonia, those receiving intensive chemotherapy (eg, high-dose cytarabine) resulting in substantial mucosal damage, patients receiving prior fluoroquinolone or TMP-SMX prophylaxis, those with prior history of colonization with β-lactam–resistant pneumococci or MRSA or with gram-positive bacteria in blood cultures (before identification and susceptibility testing), and those with sepsis without an identified pathogen should also be considered for vancomycin therapy.[4] The addition of vancomycin to an aminoglycoside-containing regimen should be done with caution because data support an increased risk of aminoglycoside-induced nephrotoxicity in patients receiving these agents concomitantly with vancomycin.[134] More recently, vancomycin has been shown to increase the risk of nephrotoxicity in patients receiving piperacillin–tazobactam.[135–138]

Alternatives to vancomycin with activity against gram-positive pathogens

Options exist for the treatment of invasive gram-positive infections. Linezolid is an oxazolidinone that can be administered via IV or orally. A randomized, double-blind trial comparing the use of linezolid with vancomycin for empiric therapy demonstrated comparable safety and efficacy.[139] It is associated with thrombocytopenia and secondary neutropenia, especially when given for prolonged periods (ie, >14 days according to the product's package insert). Considering the reduced bone marrow reserve in patients undergoing cancer chemotherapy, these adverse events are of particular concern. In addition, it is currently not recommended for patients with catheter-related infections (including bacteremia). The emergence of linezolid-resistant enterococci is of concern in this patient population. Therefore, its primary role in this patient population would be as a treatment for select gram-positive infections (such as suspected or documented MRSA pneumonia or infections due to VRE). Tedizolid, an oxazolidinone for IV and oral therapy, has more recently been approved in the United States. Although advantages over linezolid include a potential reduction in hematologic adverse events and drug

interactions, data are lacking to support tedizolid use in this population. In addition, tedizolid is not currently recommended in patients with neutropenia.

Quinupristin–dalfopristin is available for IV administration only, and concerns about potential drug interactions and patient tolerability (including myalgias and arthralgias) limit its use as empiric therapy in this setting. Daptomycin provides potent in vitro activity against many multidrug-resistant gram-positive pathogens (including VRE and MRSA). Compared to historical controls treated with vancomycin, daptomycin use in patients with cancer with gram-positive catheter-related bacteremia was associated with earlier and overall improved response.[140],[141] Daptomycin requires IV therapy, and should not be used for the treatment of pneumonia. Tigecycline possesses activity in vitro against both MRSA and VRE (in addition to many gram-negative and anaerobic pathogens). However, it lacks activity against *P. aeruginosa,* and therefore would not be considered a viable option for empiric monotherapy. Telavancin is a new lipoglycopeptide with potent activity in vitro against select gram-positive pathogens (including MRSA). However, experience to date in this population has not been published. Ceftaroline is a cephalosporin with activity against MRSA recently approved for the treatment of complicated skin and skin structure infections and community-acquired pneumonia. However, reports of the use of ceftaroline in this patient population are sparse. In addition, ceftaroline has infrequently been associated with neutropenia, most notably at higher doses and/or for prolonged courses of therapy.[142–144] Data are also lacking for the use of oritavancin and dalbavancin (also approved for IV therapy of MRSA infections) in these patients. Therefore, these alternative agents (daptomycin and linezolid) are generally reserved for situations in which vancomycin is inappropriate (because of resistance or intolerance).[2]

In the case of B.L., empiric use of vancomycin is not warranted based on the previous discussion and it should be discontinued unless cultures indicate the need for this antibiotic.

ANTIBIOTIC DOSING, ADMINISTRATION, AND MONITORING CONSIDERATIONS

Intermittent Versus Continuous Versus Prolonged Infusion of Intravenous Antibiotics

Case 75-2, Question 4: Should B.L.'s antibiotics be given intermittently (ie, divided doses) or as a continuous infusion?

β-Lactam antibiotics exhibit time-dependent (ie, concentration independent) pharmacodynamic activity, and in vitro models of infection suggest that prolonged exposure of bacteria to drug concentrations above the minimum inhibitory concentration is linked with improved bacterial killing and survival. On the basis of these observations and the poor prognosis of neutropenic cancer patients with bacteremia, noncomparative, open-label trials were conducted to evaluate the role of continuous infusions of β-lactams (ie, ceftazidime) in the empiric treatment of suspected infection in patients with cancer.[145–147] Additional studies in patients with febrile neutropenia have also been performed with meropenem, suggesting a potential benefit of prolonged infusion over traditional administration.[148] However, this method of administration would require an IV line dedicated for continuous drug administration and limit B.L.'s ability to receive intermittent tobramycin infusions unless additional IV ports or lines are available for use. In contrast to continuous infusions, prolonged infusions (ie, 3–4 hours) of select β-lactams (notably carbapenems, third- or fourth-generation cephalosporins, or piperacillin–tazobactam) have shown promise in a variety of pharmacodynamic models of infection (specifically with elevated minimum inhibitory concentrations) and tend to show better outcomes in observational studies. However, this has not been verified in prospective randomized controlled trials. Prolonged infusions of β-lactams also have the potential to reduce the total

dose, and therefore result in drug acquisition cost savings. Although only limited clinical data exist to support this kind of a strategy, such evaluations have not been tested specifically in the setting of infections in the neutropenic host.

Consolidated Interval Aminoglycoside Dosing

Case 75-2, Question 5: What is the role of consolidated (once-daily) aminoglycoside dosing in patients with febrile neutropenia such as B.L.?

Because of the concentration-dependent pharmacodynamic properties of aminoglycosides and the convenience of administration, studies have been conducted to describe both the pharmacokinetic properties and efficacy of consolidated dosing of aminoglycosides in animals and in patients with neutropenia. Pharmacokinetic studies with amikacin[149,150] and gentamicin[151,152] have not revealed pharmacokinetic differences when compared with other populations. Several clinical studies have included consolidated aminoglycoside dosing for amikacin, gentamicin, and tobramycin.[153] However, most of the studies in this population were not designed to evaluate differences between consolidated aminoglycoside dosing compared with similar regimens using intermittent dosing. In general, the various studies suggest that consolidated dosing is as effective and possibly less nephrotoxic than is traditional dosing. Therefore, consolidated dosing of aminoglycosides appears reasonable in empiric therapy of patients with neutropenia.[153]

HOST FACTORS INFLUENCING RESPONSE TO THERAPY

Case 75-2, Question 6: What factors may have influenced B.L.'s clinical response to antimicrobial therapy?

The most important prognostic determinants of a favorable outcome in patients with neutropenia and infection are the recovery of the granulocyte count and (for the patient with infection) proper selection of antimicrobial therapy. Patients with profound, persistent neutropenia (<100 cells/μL) that does not rise during therapy or an initial ANC of 100 to 500 cells/μL that declines during therapy respond to antibiotics less favorably than in patients whose bone marrow recovers. The initial granulocyte count appears to be less important than is the trend toward granulocyte recovery. Although other evidence of bone marrow recovery (such as the absolute phagocyte count, absolute monocyte count, or reticulocyte fraction) may precede the ANC target of 500 cells/μL by several days, they are not as widely used clinically. The site of infection also influences outcome. Septic shock and pneumonia are associated with high mortality in patients with bacteremic neutropenia.

MODIFYING INITIAL EMPIRIC ANTIBIOTIC THERAPY

CASE 75-3

Question 1: M.H., a 24-year-old female with a recent diagnosis of ovarian cancer, exhibited neutropenia (ANC <150 cells/μL) after chemotherapy. Five days after becoming neutropenic, she experienced a fever of 101 °F (38.3 °C) and was started on an empiric antibiotic regimen of cefepime 2 g IV every 8 hours. Although she remained febrile, her initial cultures remained negative at 48 hours.

Should M.H. be continued on the same regimen, or should modifications be made? How do the culture results influence this decision? How long should empiric therapy be continued?

The need for modification of the initial empiric therapy is dependent on the risk group (ie, low vs high risk), establishment of an infection site or causative pathogen, response to initial therapy, and clinical stability. In the absence of an identification of the infection site, worsening of clinical status, or onset of new signs and symptoms of infection, 3 to 5 days of empiric treatment are generally required to determine initial efficacy after initiation of empiric antibiotics.[4] Defervescence in patients with hematologic malignancies, as well as HSCT recipients, may be delayed (up to 5 days). During this time, daily assessments should include history and physical examinations, review of laboratory results, assessment of response, and evaluation of any antibiotic-related toxicity. Adjustments to initial empiric antibiotic therapy should be made if a site-specific infection is identified, antimicrobial resistance is suspected or documented, or the patient's condition deteriorates.

Premature discontinuation of antibiotics may predispose these patients to recrudescence of bacterial infection and increase the risk of infection-related morbidity and mortality. Patients with cancer with unexplained fever who became afebrile after empiric antibiotics were randomly assigned to continue or discontinue antibiotic therapy after 7 days.[154] The patients whose neutropenia resolved had no infectious sequelae regardless of whether antibiotics were continued or discontinued. However, for patients with persistent neutropenia randomly assigned to continue or discontinue antibiotic therapy until their ANC was >500 cells/μL, the percentages of patients remaining febrile without infectious complications were 94% and 41%, respectively. Therefore, initial empiric therapy in responding patients without an identified source should be continued until the patient's ANC is >500 cells/μL and increasing, and the patient is well and afebrile for at least 24 hours. Patients who are afebrile and stable but whose neutropenia persists may be considered for continuation with oral antibiotics (such as ciprofloxacin plus amoxicillin-clavulanate). Patients whose initial empiric regimen appropriately included vancomycin should continue receiving such therapy. In contrast, those initiated inappropriately on vancomycin, or in whom culture,

diagnosis, or condition does not support continued use should have the vancomycin therapy discontinued.

Documented Infections

Case 75-3, Question 2: On day 3, M.H.'s temperature is normal (97.6 °F [36.4 °C]). However, two sets of blood cultures drawn 3 days ago have grown *S. aureus* resistant to methicillin and susceptible to vancomycin. Her ANC is 170 cells/μL. How should therapy be modified in M.H.? For how long should antibiotics be continued?

As previously stated, modification of initial empiric therapy should be made based on culture results as well as site-specific signs and symptoms of infection (**Table 75-1**). For example, anaerobic coverage (often with a carbapenem or piperacillin–tazobactam if not used for initial monotherapy) may be expanded in the setting of abdominal pain. Oral vancomycin should be initiated in the setting of diarrhea when *C. difficile* is suspected.[4] Vesicular lesions may be suggestive of viral infections (such as HSV or VZV) and may respond to the addition of acyclovir.[1] Suspected IV catheter infections should be managed with catheter removal (whenever possible), and this as well as skin and skin structure infections should be managed with treatment directed at MRSA.[4] For pneumonia, antibiotic coverage should be consistent with published guidelines (see Chapter 67, Respiratory Tract Infections).[155,156] In the setting of severe or life-threatening pulmonary infections, antifungal therapy should also be included (Table 75-1). Modifications of therapy may also be based on isolation of a resistant pathogen. For example, resistant gram-positive infections such as MRSA may be treated with vancomycin, linezolid, or daptomycin, whereas linezolid or daptomycin may be used for the treatment of VRE. For multidrug-resistant gram-negative pathogens, carbapenems are often used to treat ESBL-producing organisms, whereas carbapenem-resistant Enterobacteriaceae may require therapy with newer β-lactam/ β-lactamase combinations, polymyxin, colistin, or tigecycline.

Table 75-1
Antimicrobials in Patients With Neutropenia and Fever[a]

Condition	Therapy[b]
Initial Empiric Therapy (Site Unknown)	
Low-Risk (Anticipated Neutropenia ≤7 Days, Clinically Stable, No Medical Comorbidities)	
Candidate for oral therapy	Adults: ciprofloxacin[a] + amoxicillin–clavulanate (alternative is clindamycin if penicillin allergic), moxifloxacin, levofloxacin Children: cefixime
Requires IV therapy	(See *High-Risk* subsequently)
High-Risk (Anticipated Neutropenia >7 Days, Clinically Unstable, Or Medical Comorbidities)	
	Piperacillin–tazobactam, antipseudomonal carbapenem,[c] or cefepime Clinically unstable: Consider addition of aminoglycoside, fluoroquinolone, or vancomycin to above mentioned regimen.
Modifications of Initial Therapy	
Unexplained Fever	
Defervescence with negative culture results	Continue antibiotics. Low-risk patients: If IV therapy initially, consider switch to oral therapy.
Persistent fever (2–4 days) without clinical or microbiologic evidence of infection	Clinically stable: Continue antibiotics.
	Unstable: Hospitalize (if outpatient), IV therapy (if initially treated with oral), broaden antibacterial coverage to include anaerobes, resistant gram-negative rods, and resistant gram-positive organisms. Consider antifungal therapy for *Candida* species, or antimold therapy if previously receiving azole prophylaxis.

Condition	Therapy[b]
	Consider empiric antifungal therapy on days 4–7, especially if neutropenia is expected to continue >7 days or the patient has other risk factors for fungal infections.
	If initial regimen did not include vancomycin: Reevaluate risk factors for gram-positive infection, consider adding vancomycin.
Documented Infection(s)	
Multidrug-resistant pathogen	MRSA: Add vancomycin, linezolid, or daptomycin. VRE: Add linezolid or higher doses of daptomycin. ESBLs: Switch to a carbapenem, carbapenemase-producing Enterobacteriaceae (other than KPC): polymyxin-colistin or tigecycline.
Head, Eyes, Ears, Nose, Throat	
Necrotizing ulceration	If initial regimen did not include anaerobic therapy (carbapenem or β-lactam/β-lactamase inhibitor; ie, piperacillin–tazobactam), consider adding clindamycin or metronidazole or switch to antipseudomonal carbapenem (imipenem–cilastatin or meropenem). Consider adding antifungal and antiviral therapy for HSV.
Oral vesicular lesions	Add antiviral therapy for HSV.
Oral thrush	Add antifungal therapy (fluconazole). Consider extended-spectrum azoles (posaconazole, voriconazole) or an echinocandin if refractory to fluconazole.
Esophagus	(See antifungal therapy for oral thrush.) Consider acyclovir for HSV if laboratory or clinical suspicion of disease. Assess CMV risk and (if high) consider ganciclovir or foscarnet.
Sinus tenderness, periorbital cellulitis, nasal ulceration	If suspicion of mold infection: Add lipid-based formulation of amphotericin B. Reassess antistaphylococcal activity of empiric regimen; consider vancomycin. Vancomycin for periorbital cellulitis
Gastrointestinal Tract	

Condition	Therapy[b]
Acute abdominal pain/perianal	If initial regimen did not include carbapenem or β-lactam/β-lactamase inhibitor (ie, piperacillin–tazobactam), consider adding metronidazole, or switch to imipenem–cilastatin or meropenem. Ensure pseudomonal coverage for perirectal infection. For perirectal pain: Consider enterococcal coverage for infection (not colonization). Consider antifungal.
Diarrhea	If *Clostridioides difficile* documented, discontinue unnecessary antibiotics and add oral vancomycin or fidaxomicin. Contact isolation of rotavirus or norovirus documented
Respiratory Tract	
Pneumonia	Add fluoroquinolone, azithromycin, or doxycycline for atypical pathogens *(Mycoplasma, Legionella).* Add vancomycin or linezolid. (Note: daptomycin is *not* indicated for pneumonia due to inactivation by lung surfactant.) For patients with additional (pathogen-specific) risk factors or clinical/lab evidence of infection: Consider the addition of a mold-active antifungal (seasonal) Consider oseltamivir against influenza. PCP: Institute TMP-SMX or (atovaquone, dapsone, or pentamidine for patients who are sulfa allergic). CMV: Add ganciclovir if high risk Consider growth factors (G-CSF, GM-CSF)
Vesicular lesions	HSV, VZV treatment: acyclovir, famciclovir, or valacyclovir
Cellulitis, wound infection	Consider adding vancomycin (or alternative MRSA) therapy
Vascular access device infection, tunnel tract infection	Remove catheter whenever possible. Add empiric vancomycin (or alternative MRSA) therapy. Adjust based on culture and susceptibility results.
Documented Infection(s) (continued)	
Central nervous system	Antipseudomonal β-lactam (cefepime or meropenem) + vancomycin. Add ampicillin if meropenem is not used.
Encephalitis	High-dose acyclovir

Condition	Therapy[b]
Urinary tract	Change based on pathogen identification and susceptibility.
Bloodstream infections	Gram-negative: Add aminoglycoside and switch to antipseudomonal carbapenem. Gram-positive: Add vancomycin, linezolid, or daptomycin.

CMV, cytomegalovirus; ESBL, extended-spectrum β-lactamase; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HSV, herpes simplex virus; IV, intravenous; KPC, *Klebsiella*-producing carbapenemases; MRSA, methicillin-resistant *Staphylococcus aureus;* PCP, *Pneumocystis jiroveci;* TMP-SMX, trimethoprim–sulfamethoxazole; VRE, vancomycin-resistant enterococcus; VZV, varicella zoster virus.

[a]Exclude option if patient received fluoroquinolone prophylaxis.

[b]All modifications should be based on clinical and microbiologic data.

[c]Antipseudomonal carbapenem is imipenem–cilastatin or meropenem.

Freifeld A, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;52:e56–e93; Taplitz RA, Kennedy EB, Bow EJ, et al. Outpatient management of fever and neutropenia in adults treated for malignancy: American Society of Clinical Oncology and Infectious Diseases Society of America clinical practice guideline update. *J Clin Oncol*. 2018;36(14):1443–1453. doi:10.1200/JCO.2017.77.6211.

The duration of therapy is based on the infecting organism and site of infection (often up to 14 days) and should continue at least until the ANCs are ≥500/μL and rising.[4]

For patients with documented infections unresponsive to modification of therapy, new or worsening sites of infection should be suspected. Clinical, laboratory, and radiographic investigations should be undertaken or repeated. For hemodynamically unstable patients, antimicrobial therapy should be broadened, and the patient should be considered for empiric antifungal therapy.[4]

No Etiology Identified

CASE 75-4

Question 1: S.B. is a 55-year-old female with chronic myelogenous leukemia. She was admitted to the hospital with a 4-day history of fevers and night sweats. On admission, her temperature was 102.3 °F (39.1 °C), and her WBC count was 100,000 cells/μL, with an ANC of 500 cells/μL. Blood and urine cultures were obtained, and cefepime was empirically started. For the next 3 days, S.B. remained persistently febrile and neutropenic. All culture results remained negative.

How should she be treated?

Persistent fevers may be from noninfectious sources or from untreated infection. With the exception of consideration for antifungal therapy in some patients, those with persistent fever who are clinically stable do not routinely require a change in empiric therapy unless guided by clinical changes or culture results.[2] However, outpatients with persistent fever should be hospitalized and receive IV therapy. Empiric addition of vancomycin in patients with persistent fever does not decrease the time to fever resolution in this population,[157] and should therefore be discouraged.[2] In contrast, persistently febrile patients who are hemodynamically unstable without a clear source of infection should have their initial therapy modified to broaden coverage against resistant gram-positive and gram-negative organisms, as well as anaerobes. Patients with initial monotherapy with cefepime can be switched to vancomycin with an antipseudomonal carbapenem (such as imipenem–cilastatin or meropenem) in combination with either an aminoglycoside, aztreonam, or ciprofloxacin. Antifungal therapy targeting *Candida* species should also be considered (see Case 75-4, Question 3).

Case 75-4, Question 2: S.B., on day 4, continues to feel "lousy" and has started to report abdominal pains. What is the significance of this report? Should her antibiotic regimen be modified again?

Because S.B. has new abdominal pains suggestive of enterocolitis, her antibiotic regimen should be modified. Although cefepime provides excellent coverage against the common gram-negative pathogens, it has limited activity against select gram-

positive pathogens (eg, MRSA or VRE) and anaerobes. A change from cefepime to imipenem–cilastatin or another broad-spectrum regimen with both aerobic and anaerobic activity should be considered.

Case 75-4, Question 3: S.B.'s antibiotic regimen was changed to imipenem–cilastatin. Despite the change, she continues to have a low-grade fever and does not feel better. What is S.B.'s risk of having a systemic fungal infection? What is the significance of fungal infections in neutropenic cancer patients?

ANTIFUNGAL THERAPY

Early diagnosis and prompt treatment of systemic fungal diseases are critical to patient survival. However, significant challenges exist in making an accurate and timely diagnosis of IFIs. Therefore, patients who are neutropenic with protracted (4–7 days) fever despite the administration of broad-spectrum antibiotics should be considered for empiric antifungal therapy, especially patients whose neutropenia is anticipated to exceed 7 days.[2,158] Patients at highest risk for mold infections (ie, those with prolonged neutropenia, allogeneic HSCT recipients, and/or those receiving high-dose corticosteroids) should be initiated on antifungals after 4 days of persistent fever unless they are currently receiving antimold prophylaxis. Considerations for earlier empiric antifungal therapy (ie, days 2–4) should be made in patients with persistent fever and hemodynamic instability.[4]

Newer diagnostic tests (eg, β-D-glucan tests or galactomannan assays), along with additional diagnostic support, may allow for early preemptive therapy (ie, institution of therapy based on biomarker evidence of disease before the development of symptoms).[159] Such approaches may also be used to support decisions to withhold empiric antifungal therapy. As an example, persistently febrile patients on appropriate antibacterials who are clinically stable without clinical or radiographic signs of fungal infection, have had negative serologic assay results for IFI, and have had no recovery of fungi from any body site may have empiric antifungal agents withheld.[4,99]

Considerations about the choice of empiric antifungals should include prior or current antifungal prophylaxis, risk of mold infections, risks of antifungal-related toxicities, drug interactions, route of administration, clinical stability, and costs.[19] It is difficult to compare data among clinical trials evaluating empiric antifungal therapy in neutropenic cancer patients because of differences in trial design. Such differences may include inclusion of low-risk patients, lack of blinding, changes in concomitant antibacterials obscuring antifungal therapy end points, prior antifungal prophylaxis, use of composite end points of safety and efficacy, and different end point criteria.[20] Although select studies have also demonstrated that empiric antifungal therapy can decrease fungal-related deaths, overall mortality has not been affected.[19] This is the case particularly for patients with invasive disease and persistent neutropenia.

In patients requiring therapy, antifungal coverage should be directed at *Candida* species. Highest risk patients with persistent or recurrent fever after 4 to 7 days of appropriate antibacterial therapy and anticipated to have prolonged (ie, >10 days) neutropenia should be considered for antimold therapy.[4]

CASE 75-4, QUESTION 4: Should amphotericin B or acyclovir therapy be considered in S.B.?

Historically, AmBd was most commonly used in this setting because of its reliable activity in vitro against most *Candida* and *Aspergillus* species. Comparative trials have also evaluated the role of lipid-based formulations of amphotericin B in the treatment of suspected or documented infections in this population. LAmB,[160–163] amphotericin B lipid complex,[162] and amphotericin B colloidal dispersion[164] have demonstrated reductions in nephrotoxicity compared with AmBd. In addition, LAmB is least likely to be associated with infusion-related side effects.[161] Although there are limited data to suggest that the continuous infusion of AmBd may also reduce nephrotoxicity,[165] efficacy regarding this method of administration in patients with documented infections has not been

established. Therefore, continuous infusion of AmBd cannot be routinely recommended at this time. Considering the availability of other agents, empiric amphotericin B products are generally reserved for patients at highest risk for mold infections unable to receive alternative antifungals. When initiated as empiric therapy, amphotericin B administration is often preceded by attempts to minimize nephrotoxicity (eg, saline loading) and premedications to minimize infusion-related reactions. Close monitoring of tolerability, renal function, and electrolytes is required during administration.

In stable patients at low risk for mold infections or drug-resistant *Candida* species (eg, *C. krusei* and some strains of *C. glabrata*), fluconazole may be preferable to amphotericin B.[4,166,167] Patients with suspected mold infections (eg, aspergillosis), hemodynamic instability, or in whom an azole was used as prophylaxis should not receive fluconazole. Although itraconazole possesses enhanced activity in vitro against *Aspergillus* species and has reduced toxicity relative to amphotericin B, issues regarding tolerability with the oral solution, erratic bioavailability with the capsule formulation, potential for cross-resistance with other azoles, lack of a parenteral treatment option, and considerations of alternative treatment options generally limit its usefulness. A new formulation of itraconazole (SUBA-itraconazole) demonstrates improved absorption after oral administration. Posaconazole possesses a broad spectrum of activity in vitro against a variety of yeasts and molds. It is currently available in both an oral and IV formulation. Voriconazole (an azole antifungal agent with increased activity against *Aspergillus* and non-albicans *Candida* relative to fluconazole) has been tested in this population. When compared with LAmB, voriconazole failed to meet the preestablished criteria for noninferiority.[163] However, some believe that voriconazole should be considered as an alternative to amphotericin B preparations for empiric therapy in patients requiring initial empiric antifungal therapy who are at increased risk for mold infections (owing to receipt of prior azole prophylaxis) or for those patients suspected of having invasive candidiasis.[158] Because of the increased potential (relative to fluconazole) for drug interactions (including immunosuppressives and chemotherapy) and adverse

events (eg, phototoxicity, hepatotoxicity), voriconazole therapy should be monitored closely. IV use of voriconazole is contraindicated in patients with severe renal dysfunction. In addition, serum drug concentration monitoring for itraconazole, posaconazole, and voriconazole should be considered in select, high-risk patients receiving these triazoles to ensure adequate target concentrations.[4,8] These agents demonstrate significant intra- and interpatient variability in serum concentrations secondary to alterations in absorption, metabolism, elimination, or drug–drug interactions. Drug- and indication-specific recommended target concentrations for the triazoles are discussed extensively elsewhere.[49] Briefly, samples for analysis are obtained once steady state has been achieved (usually 5–7 days after initiation of therapy) before the next dose (trough concentration). Typical drug serum concentration for the treatment of IFIs include 1 to 2 μg/mL (toxicity >5 μg/mL) for itraconazole, >0.7 μg/mL (toxicity not established) for posaconazole, and >1 μg/mL (toxicity >5 μg/mL) for voriconazole.

Most recently, isavuconazole has been FDA approved for both oral and IV administration for the treatment of invasive aspergillosis and mucormycosis.[168] Potential advantages (relative to voriconazole) include improved oral bioavailability, predictable pharmacokinetics (no need for serum drug monitoring), and a reduction in the potential for drug interactions. For treatment of invasive aspergillosis, isavuconazole's efficacy was noninferior to that of voriconazole.

The echinocandins (eg, caspofungin, micafungin, anidulafungin) possess in vitro activity against *Candida* species (including non-albicans *Candida*) and *Aspergillus* species. Caspofungin is at least as effective and better tolerated than is LAmB as empiric therapy in this patient population.[169,170] Because of their safety profile and in vitro activity, echinocandins are often considered for patients requiring initial empiric antifungal therapy and who are at increased risk for mold infections (owing to receipt of prior azole prophylaxis). Caspofungin is currently FDA approved for such use. Published experience with other echinocandins (eg, micafungin, anidulafungin) as empiric therapy in the patient with febrile neutropenia is lacking at present; however, many would consider them interchangeable.

In summary, empiric antifungal therapy is indicated for persistent (4–7 days) or recurrent fever on appropriate antibacterials if the duration of neutropenia exceeds 7 days. Low-risk patients who are clinically stable do not routinely need antifungal therapy. Persistently febrile patients who are clinically stable without computed tomography signs of infection and have no serologic or culture results suggestive of infection may have antifungal therapy withheld. Patients receiving fluconazole prophylaxis requiring the addition of empiric antifungals should be considered for antifungals with activity against azole-resistant *Candida* species and mold infections. In the setting in which an antimold agent was used for prophylaxis, switching antifungal classes or conversion to IV therapy should be performed.

ANTIVIRAL THERAPY

Empiric use of antiviral agents in the patient with febrile neutropenia is not indicated without evidence of such disease.[4] In contrast, clinical evidence of HSV or VZV involving the skin or mucous membranes should be treated with antivirals (eg, acyclovir, valacyclovir).[4] When oral therapy is used, valacyclovir is favored over acyclovir because of improved oral bioavailability and need for less frequent dosing. With the exception of patients undergoing bone marrow transplantation,[171] CMV is an uncommon source of infection in the patient with febrile neutropenia. However, ganciclovir, valganciclovir, foscarnet, or, less commonly, cidofovir treatment should be initiated in patients with documented CMV infections (antigenemia, PCR for CMV DNA, or detection of CMV mRNA). Because both ganciclovir and valganciclovir can cause or worsen existing neutropenia, caution and close monitoring is warranted when these agents are prescribed in this setting. Treatment with neuraminidase inhibitors (such as oseltamivir or zanamivir) may be initiated empirically for influenza in the setting of exposure or outbreaks if the patient is presenting with an influenza-like illness.[4] Peramivir IV may be used in individuals unable to take oral oseltamivir or inhaled zanamivir. Baloxavir may be effective in this

population; however, its role is yet to be determined. Likewise, if RSV is identified, appropriate antiviral therapy should be initiated.[4]

ANTIMICROBIAL ADJUVANTS

CASE 75-4, QUESTION 5: S.B. became afebrile 2 days after micafungin was initiated, yet she remained neutropenic with an ANC of 480 cells/μL. An induction chemotherapy regimen consisting of idarubicin plus cytarabine was initiated for her chronic myelogenous leukemia. Because the chemotherapy will further reduce her ANC 7 to 10 days after treatment, is there any way to facilitate marrow recovery and reduce the duration of neutropenia in S.B.?

As previously discussed, the duration of neutropenia is the most important factor affecting outcome in neutropenic cancer patients. Because of this, there has been considerable interest in enhancing the immune system in these patients.

Granulocyte Transfusions

One of the earliest approaches used to boost the patient's defense against infections was the transfusion of WBCs. In the 1970s, granulocyte transfusions were used adjunctively in patients with persistent neutropenia and documented infections who, despite appropriate antibiotics, failed to respond after 24 to 48 hours. This approach had limited value because of the difficulties in obtaining adequate cells for transfusion, as well as the problems with alloimmunization and risk of infection transmission. In addition, the questionable efficacy of WBC transfusions has decreased the use of this strategy.[172] Therefore, granulocyte transfusions are not routinely indicated in this population. However, patients with progressive bacterial or fungal infections unresponsive to appropriate antimicrobial therapy may be considered as candidates.

Hematopoietic Growth Factors

Because these agents have not demonstrated a consistent and significant effect on other infection-related parameters (eg, duration of fever, use of antibiotics, costs of treatment), the use of CSFs as adjunctive therapy to antibiotics for patients with febrile neutropenia is controversial.[4,28] Patients already receiving CSFs for primary or secondary prevention may be continued during treatment of febrile neutropenia. Those patients administered pegfilgrastim for primary or secondary prevention should not require subsequent doses of CSFs because of the persistence of high CSF concentrations for prolonged periods.

Patients at high risk for infection-related complications not receiving CSFs for prophylaxis may be considered for therapy. Such risks include expected prolonged (>7 days) and profound (<100 cells/μL) neutropenia in clinically unstable patients unresponsive to initial empiric therapy, age older than 65 years, uncontrolled malignancy, pneumonia, sepsis and multiorgan dysfunction (characteristic of sepsis syndrome), and IFI.[9]

Immunoglobulins

Data regarding the use of Igs as adjunctive therapy for the treatment of select infections in the neutropenic cancer patient are primarily limited to case reports. Patients with pneumonia secondary to CMV may benefit from adjunctive Ig therapy (in combination with ganciclovir). In addition, IVIG should be considered in those patients with hypogammaglobulinemia.

G-CSF administration, although likely to reduce the duration of her chemotherapy-induced neutropenia, is not indicated in S.B., who is otherwise stable.

Pharmacotherapy of Human Immunodeficiency Virus Infection

Aaron S. Devanathan, Allison E. Symonds, Jessica L. Adams, and Mackenzie L. Cottrell

CORE PRINCIPLES		CHAPTER CASES
1	Acute retroviral syndrome is characterized by nonspecific symptoms, such as fever, lymphadenopathy, rash, fatigue, and night sweats that coincide with an initial burst of viremia. These symptoms, as well as the presence of an opportunistic infection, and high-risk sexual or drug-using behaviors, warrant human immunodeficiency virus (HIV) testing. With current antigen/antibody laboratory tests, HIV can be diagnosed as early as 2 weeks after infection. In patients in whom very early infection (older than 2 weeks) is suspected, nucleic acid tests for HIV RNA may be considered for diagnostic purposes.	**Case 76-1 (Question 1)**
2	HIV RNA viral load is measured to quantify the level of viral replication in the body, and CD4 cell counts are followed to assess immune system function.	**Case 76-1 (Question 2)**
3	Antiretroviral therapy (ART) should be initiated as soon as possible after diagnosis in all patients after discussion of the lifelong benefits and importance of adherence. Early ART initiation is especially important in the following clinical situations:	**Case 76-1 (Question 3)**

	acquired immunodeficiency syndrome (AIDS)-defining condition such as an opportunistic infection, acute/recent HIV infection, and pregnancy. U.S. Department of Health and Human Services (DHHS) guidelines provide recommendations for optimal ART.	
4	Goals of ART include suppression of viral load, preservation and strengthening of the immune system, limitation of drug adverse events, promotion of adherence, prevention of HIV-related morbidity and mortality, prevention of HIV transmission, and reduction of latent reservoir.	**Case 76-1 (Question 4)**
5	General rules of therapy involve selection of ART-based regimen, optimization of the selected agents, and inclusion of quality of life in decisions.	**Case 76-1 (Questions 5, 6)**
6	After initiating an ART regimen, short-term goals include resolution of symptoms, undetectable HIV RNA levels at 8 to 24 weeks, and an increase in CD4 count at 3 to 4 months. Long-term assessments include the monitoring of HIV RNA and CD4 count every 3 to 6 months—and potentially every 12 months—to identify treatment failures, assessment of medication adherence, and determination of tolerability and quality of life.	**Case 76-1 (Questions 7, 8)**
7	General rules for changing failing regimens include switching to at least two new active drugs (although all new drugs are preferable), as quickly as possible after treatment failure to avoid accumulation of resistance mutations. To avoid the development of further resistance, a single drug should never be added to a failing regimen. If one drug must be discontinued, the whole regimen should be stopped simultaneously. Finally, previously failed regimens should never be restarted because of the potential of archived resistance mutations.	**Case 76-1 (Questions 9, 10)**
8	Considerations for treatment of antiretroviral-experienced patients include regimen tolerability, comorbid conditions, associated pharmacokinetic properties, antiretroviral histories, and resistance testing. Resistance testing should be performed	**Case 76-2 (Questions 1–3)**

	only when HIV RNA is >1000 copies/mL because of assay sensitivity constraints. Antiretroviral drug resistance is assessed through two methods: genotyping evaluates mutations in the virus genetic code and phenotyping involves growing virus in various concentrations of drug to determine viral susceptibilities. DHHS guidelines provide recommendations for treating antiretroviral-experienced patients.	
9	Drug interactions between ART and coadministered medications are common with certain classes of ART and should always be screened with the addition of any new medication.	**Case 76-3 (Question 1)**
10	ART is used in pregnancy for the health of the mother and to prevent transmission of HIV to the child. There are specific DHHS guidelines for antiretroviral use in pregnancy.	**Case 76-4 (Question 1)**
11	The use of ART for preexposure prophylaxis (PrEP) in individuals who are HIV-negative, but at high risk for acquiring HIV, has been shown to be safe and effective in clinical studies. Two combination products of emtricitabine with tenofovir disoproxil fumarate (FTC/TDF) or with tenofovir alafenamide (FTC/TAF) are Food and Drug Administration (FDA)-approved for this use, and the Centers for Disease Control and Prevention (CDC) and International AIDS Society–USA Panel have issued guidelines on the use and monitoring of the combination for this indication. Importantly, FTC/TAF is not recommended for use in cisgender females to prevent HIV acquisition through vaginal transmission.	**Case 76-5 (Question 1)**
12	The use of ART for occupational (eg, needle sticks) and nonoccupational (eg, high-risk behaviors) postexposure prophylaxis (PEP) may be warranted if initiated within 48 hours but no longer than 72 hours after exposure. There are CDC guideline recommendations for the choice of ART for PEP.	**Case 76-6 (Question 1)**

INTRODUCTION

Antiretroviral therapy (ART) is the combination of potent ART and has been shown to dramatically alter the natural progression of human immunodeficiency virus (HIV) infection, significantly improve patients' quality of life, and restore life expectancy of people living with HIV (PLWH) to that of an uninfected person. As a result, the number of newly acquired immunodeficiency syndrome (AIDS)– related opportunistic infections and deaths has declined.[1,2] In most instances, the use of ART has shifted HIV infection from a fatal disease to a manageable chronic disease. The most recent advances in HIV therapy include new and more potent ART in existing therapeutic drug classes, novel combinations of ART, new single tablet once-daily regimens, and the development of long-acting formulations.

Despite the drastic improvements in HIV treatment over the last decade, successfully managing the HIV epidemic remains a challenge because of suboptimal adherence to ART and the development of resistance, long-term adverse events, the price of ART, and the rampant spread of HIV throughout resource-poor countries.

This chapter focuses on the antiretroviral treatment of HIV infection. Although many therapeutic options now exist, a thorough understanding of viral pathogenesis is essential for managing patients infected with HIV. By understanding the principles of therapy as they relate to viral pathogenesis, clinicians can rapidly assimilate new data as they become available. Consensus panel recommendations provide a framework for clinical decision-making.[3–5] Given the complexity of therapy, this chapter focuses on treating adult HIV infections. A cursory introduction to the clinical concepts of perinatal transmission, preexposure prophylaxis (PrEP), and postexposure prophylaxis (PEP) for both occupational and nonoccupational HIV exposures are also provided. For more in-depth discussion of these concepts and the treatment of pediatric HIV, the reader is referred to the various consensus panel guidelines (https://clinicalinfo.hiv.gov/en/guidelines).

EPIDEMIOLOGY

In recent years, AIDS-related opportunistic infections and deaths in industrialized countries have dramatically declined in part because of ART and increasing access to health care.[2,6] However, access to newer, more potent antiretroviral regimens and monitoring are often limited by economics and politics. Infected patients residing in countries with a strong economic standing (North America, Western Europe, Australia, and New Zealand) have reasonable access to medications, and in recent years, patients residing in countries previously known to have scarce resources (Africa, south and southeast Asia, the Pacific, and the Caribbean) have had increasing access to medications. Regions that have made less progress are those in which the epidemic is predominantly concentrated in populations with lower access

and utilization of services, such as sex workers, injecting drug users, and males who have sex with males.[6]

As of 2019, the worldwide estimate of PLWH was 38 million: 36.2 million adults (53% of which are females) and 1.8 million children younger than age 15 years.[7] The estimated incidence (1.7 million new HIV infections) decreased by 25% from 2010, and the estimated number of AIDS-related deaths (690,000) decreased by 59%. Approximately two-thirds (68%) of all HIV-infected adults and children live in Africa, and approximately two-thirds (64%) of all AIDS-related deaths occurred there in 2019. Increasing access to HIV treatment in this region has led to a 63% reduction in the number of AIDS-related deaths since 2001. Universal access to ART became a global priority in 2000 when the United Nations Millennium Declaration called for unprecedented action to halt and begin to reverse the AIDS epidemic. This call to action resulted in an increase of more than 17.8 million PLWH in Africa (~13%) accessing ART in 2019 (increased from <1% in 2000). With these global efforts, the percentage of all PLWH worldwide on ART is 67%.

In the United States, the availability of ART resulted in a drastic decline (67%) in AIDS-related death rates between 1994 and 2007, and this percentage continues to drop albeit at a slower rate (54% decline from 2009 to 2018). Despite this success, ~7800 people in the United States still died from HIV attributable causes in 2018.[2] Racial and ethnic minorities continue to be disproportionately affected by HIV because of a complicated combination of poverty, disproportionate incarceration, and social and sexual network segregation.[8] In 2018, African Americans (who represented 13% of the U.S. population) accounted for ~42% of all new HIV infections in adult and adolescents and Hispanics/Latinos (who constitute 18% of the U.S. population) accounted for 27%. Compared with White males and females, the lifetime risk of HIV seroconversion is six times higher in African American males, 20 times higher in African American females, three times higher in Hispanic/Latino males, and four times higher in Hispanic/Latino females.[9] Gender is also an important factor linked to HIV prevalence, and transgender females are most vulnerable with a 49- to 80-fold increased risk of infection when compared to cisgender populations. Transmission through sexual intercourse remains a predominant route of infection, with rectal transmission from unprotected anal sex accounting for ~66% of cases and vaginal or penile transmission from unprotected heterosexual sex accounting for ~24% of cases in the United States.[9]

PATHOPHYSIOLOGY

Infection with HIV can be acquired through unprotected sexual intercourse (both anal and vaginal), injection drug use, receipt of tainted blood products, and mother-to-infant transmission (both perinatal infection and postpartum through breast-feeding).[3] Infection can also be acquired from occupational exposures among health care workers after needle sticks or infected blood splashes from patients infected with HIV

onto vulnerable mucosal membranes. Rarely, HIV infection has been documented following oral sex.[10,11]

Unprotected sexual intercourse accounts for ~80% of all documented HIV infections to date.[2,7] Infectivity via receptive anal intercourse represents the greatest sexual risk factor followed by male-to-female vaginal transmission and then female-to-male penile transmission.[12] Transmission between sexual partners depends on a number of factors, including the HIV viral subtype, stage of infection in the index partner, genetic susceptibility to infection of the potential host, and the viral fitness (or pathogenicity) of the infecting strain. Perhaps one of the most important predictors of transmission is the amount of HIV RNA in the blood of the infected index patient (ie, viral load). In 2011, the HPTN 052 trial demonstrated >95% reduction in risk of transmission when PLWH were started on ART immediately versus waiting for a decline in CD4 count or the onset of HIV-related symptoms. Since this landmark study, additional studies have demonstrated negligible transmission risk (0.00 transmissions/ 100 person-years with a 95% confidence interval of 0.00–0.28) from PLWH who have an undetectable viral load on ART.[13–15]

During transmission, HIV binds to specific immune cells, including Langerhans cells, dendritic cells, T-cell lymphocytes (also known as $CD4^+$ T cells, helper T cells, or T cells), and macrophages.[12,16–18] HIV primarily enters target immune cells that express specific receptor proteins known as CD4 receptors to which HIV binds. Once bound to the CD4 receptor, co-receptor proteins (CCR5, CXCR-4) are required for fusion of the viral membrane to the immune cell membrane.[19,20] CCR5 co-receptors are found on both monocytes and T lymphocytes and are more abundant in patients newly infected with HIV.[21,22] CXCR-4 co-receptors are predominantly found on T lymphocytes and are more abundant in patients who have been on long-term ART. The CD4–co-receptor complex causes conformational changes to key HIV proteins (gp41 and gp120) allowing for a more close association between the virus and the host cell.[22,23] HIV fuses with the cell and releases its contents into the host cell's cytoplasm: this includes the virus's RNA and specific enzymes necessary for replication (**Fig. 76-1**; see online animated images of HIV life cycle and where the drugs act at http://scienceofhiv.org/wp/?page_id=20). The single-stranded viral RNA is transcribed via reverse transcriptase into a double-stranded proviral DNA that is subsequently incorporated into the host cell's genetic material via the integrase enzyme. HIV then uses the infected cell's machinery to translate, transcribe, and produce immature viral particles that bud and break from the infected cell. For these immature virions to become infectious, the HIV protease enzyme must cleave large precursor polypeptides into functional proteins.[24,25] Once complete, the mature virion is free to infect new host cells and subsequently produce more infectious virus.

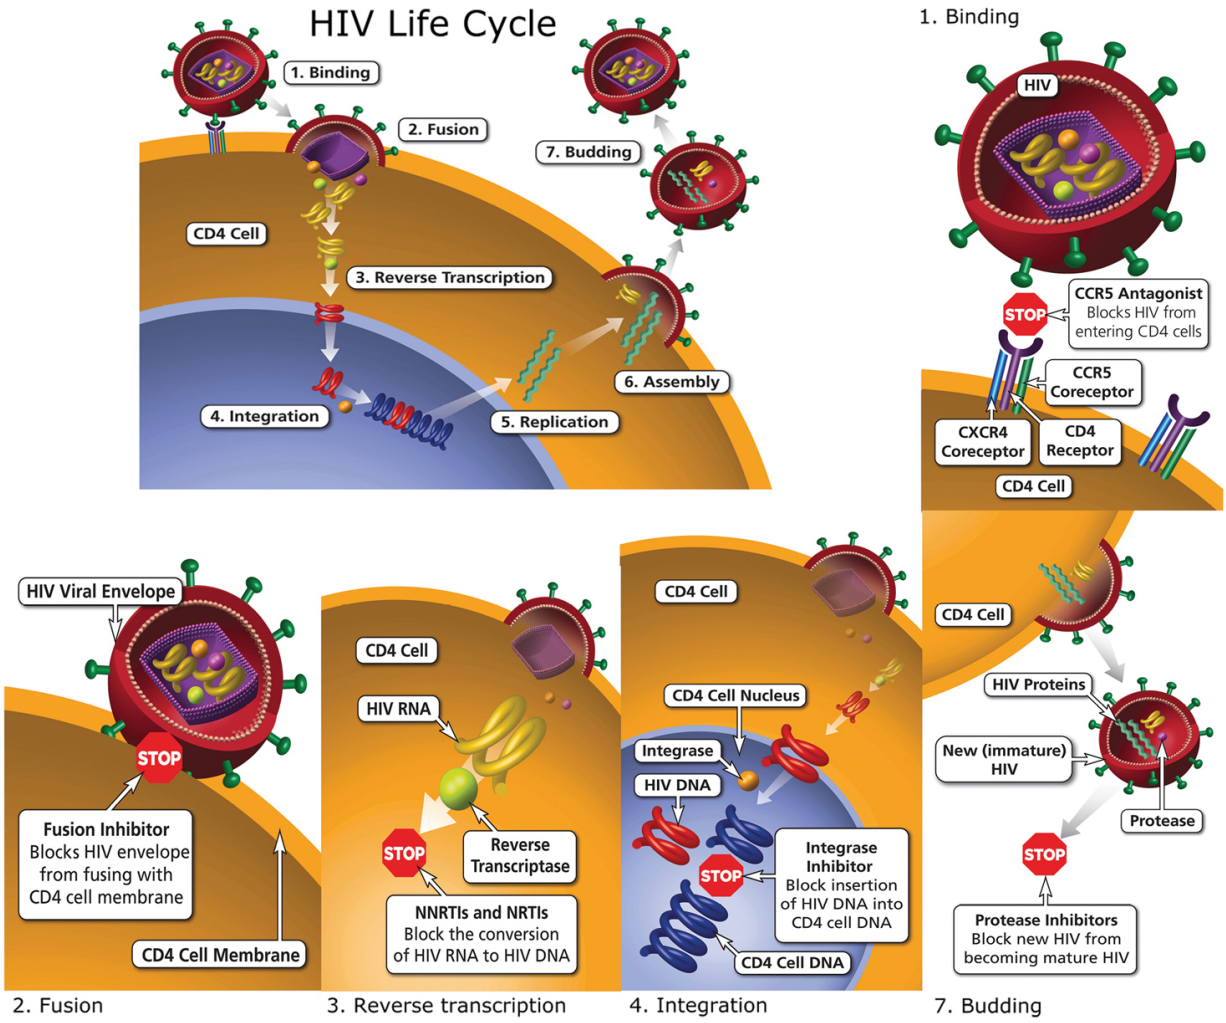

Figure 76-1 Schematic representation of the HIV-1 life cycle. Five classes of antiretroviral drugs are available at present. CCR5 antagonists and fusion inhibitors inhibit the entry of virions into a new target cell. The step of reverse transcription can be targeted, using nucleoside nucleotide analogs or non-nucleoside reverse transcriptase inhibitors (NRTIs and NNRTIs, respectively). The class of integrase inhibitors prevents integration of viral DNA into host cell DNA. The class of PIs interferes with the last state of the life cycle, the proteolytic processing of the viral proteins, which results in the production of noninfectious particles. (Adapted from education materials provided by the National Institutes of Health available on https://clinicalinfo.hiv.gov/en/guidelines.)

Over time, HIV-infected host cells can be destroyed by a number of mechanisms: (a) a direct cytolytic effect of the virus (eg, formation of syncytium induction, cellular dysfunction); (b) the identification and elimination of the infected cell by the host's immune response (eg, via cytotoxic T-cell lymphocytes); or (c) the cell's natural life cycle coming to completion.[26] In addition, HIV infection can inhibit the production of new $CD4^+$ cells.[27]

Once a patient becomes infected, an initial burst of viremia occurs and causes latent infection in various tissues (eg, lymph nodes) and cells (CD4, macrophages, and monocytes).[26,28] Most infectious HIV virions (~99%) reside inside lymph nodes and other immune-cell–rich tissues found throughout the body.[16,26,29,30] The immune system reacts by producing antibodies against HIV; however, given the rapid production of new HIV particles and the development of many new and genetically diverse viral strains (a result of the error-prone HIV reverse transcriptase), the antibody response is inadequate.[31] After this burst of viremia, a transient depletion of $CD4^+$ cells occurs (**Fig. 76-2**). Initially, patients may raise concerns of nonspecific symptoms, such as fever, lymphadenopathy, rash, fatigue, and night sweats.[3] This phase of infection is known as the acute retroviral syndrome.

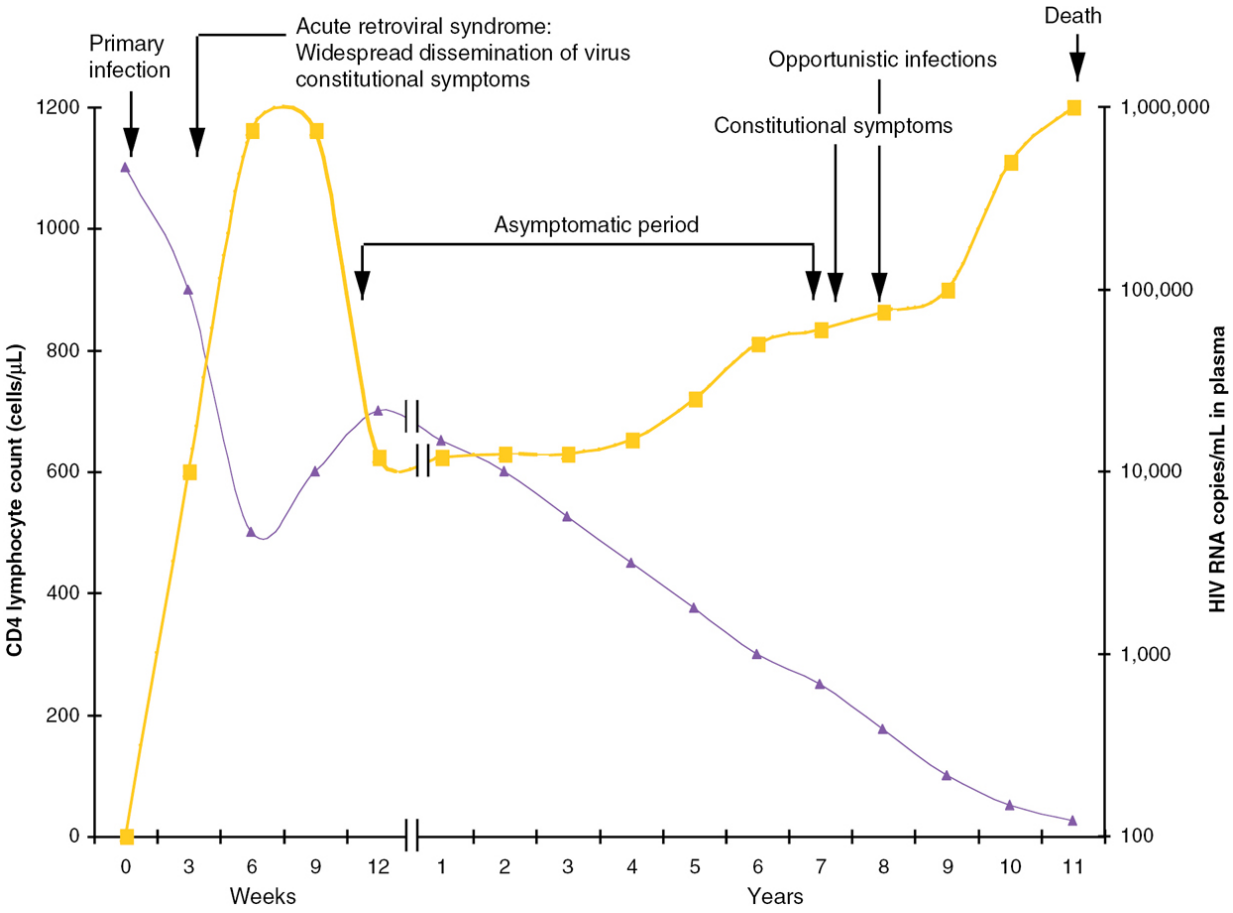

Figure 76-2 Sample disease course for an untreated HIV-infected individual showing the relationships among immunologic, virologic, and clinical outcomes over time. Constitutional symptoms include fever, night sweats, and weight loss. Viral load values; CD4 T lymphocytes. (Source: From Fauci AS, Pantaleo G, Stanley S, Weissman D. Immunopathogenic mechanisms of HIV infection. *Ann Intern Med*. 1996;124(7):654–663. © 1996 American College of Physicians. All Rights Reserved. Reprinted with the permission of American College of Physicians, Inc; Perelson AS, Neumann AU, Markowitz M, Leonard JM, Ho DD. HIV-1 dynamics in vivo: virion

clearance rate, infected cell life-span, and viral generation time. *Science.* 1996;271(5255):1582–1586.)

In most cases, patients are unaware that they are infected. Within 6 months, the host's immune response is able to control the infection to a point where the number of virus particles produced per day equals the number of particles destroyed per day. This steady state is often referred to as the patient's viral "set point."

The higher a patient's viral set point, the greater the risk for disease progression. This is because there is a greater chance for more widespread viral infection and immune cell destruction with a larger replicating viral population. Why some patients establish higher or lower viral set points is currently under investigation, but this may be a consequence of differences in immune responses, cellular receptor populations, viral subtypes, viral fitness, or a combination of these factors. This understanding of viral pathogenesis has led to a new paradigm of therapy that prioritizes initiating ART in the acute phase of infection to lower viral set points and reduce the size of the viral reservoir (ie, long-lived, latently infected memory T cells believed to be responsible for repopulating the virus in infected patients who stop ART).[3] A significant challenge is to identify these patients with acute infection who have nonspecific symptoms.[32]

Once the initial burst of viremia has been controlled and the viral set point established, infection with HIV results in a constant battle between viral replication and suppression of that replication by the immune system. Mathematical models have calculated the production of HIV at 10 billion particles per day.[16,33–35] To keep the infection controlled, the body must produce an equal immune response. Over time, HIV depletes the body of T cells, which places the host at an increased risk for opportunistic infections. Direct measurements of HIV RNA concentrations in plasma (also called "viral load") can predict disease progression (see subsequent discussion).[36–38] Higher viral load measurements represent an inability of the host to control viral replication and a greater risk for immune cell destruction. Long-term "nonprogressors" (eg, patients with asymptomatic HIV infection for >10 years; 5% of all HIV-infected patients) consistently have lower baseline viral loads than patients with rapidly progressive disease (eg, AIDS within 5 years of infection; 20% of all HIV-infected patients).[39,40]

Without intervention, the natural progression of HIV infection results in depletion of 50 to 100 T cells/μL/year.[26] The severity of immune dysfunction, as evidenced by T-cell loss, is highly predictive of the potential for the development of specific types of opportunistic infections. For example, *Pneumocystis jirovecii* pneumonia rarely occurs when T-cell counts are >200 cells/μL, whereas retinitis from cytomegalovirus infection rarely occurs in patients with CD4 counts >75 cells/μL. The diagnosis of AIDS is made when a significant amount of immune deterioration has occurred, either by depletion of $CD4^+$ cells to <200 cells/μL or because of the development of new opportunistic infections (**Table 76-1**). It is important to recognize that not every patient with HIV has a diagnosis of AIDS. On average, without appropriate drug therapy, death occurs within 10 to 15 years after infection.[26]

Table 76-1

CDC MMWR Revised Surveillance Case Definition for HIV Infection—United States, 2014

HIV infection stage[a] based on age-specific $CD4^+$ T-lymphocyte count or $CD4^+$ T-lymphocyte percentage of total lymphocytes						
Stage	Age on date of $CD4^+$ T-lymphocyte test					
		<1 year		1–5 years		≥6 years
	Cells/μL	%	Cells/μL	%	Cells/μL	%
0[b]	Staging independent of CD4 count/% and age					
1	≥1500	≥34	≥1000	≥30	≥500	≥26
2	750–1499	26–33	500–999	22–29	200–499	14–25
3	>750	>26	>500	>22	>200	>14

[a]Stage is based first on the $CD4^+$ T-lymphocyte count, and then on percentage if the count is unavailable. Three situations can dictate that staging is not based on count or percentage: (1) Stage 0 criteria are met, meaning that the stage is 0 regardless of $CD4^+$ T-lymphocyte test results and the diagnosis of opportunistic infection; (2) if the criteria for stage 0 are not met and a stage-3 defining opportunistic illness has been diagnosed (see Table 76-2), meaning that the stage is 3 regardless of $CD4^+$ T-lymphocyte test results; or (3) if the criteria for stage 0 are not met and information on the above criteria for other stages is missing, then the stage is classified as unknown.

[b]Stage 0 can be established either:

Based on testing history (previous negative/indeterminate test results): a negative or indeterminate HIV test (antibody, combination antigen/antibody, or NAT) result within 180 days before the first confirmed positive HIV test result of any type. The first positive test result could be any time before the positive supplemental test result that confirms it.

Based on a testing algorithm: a sequence of tests performed as part of a laboratory testing algorithm that demonstrate the presence of HIV-specific viral markers such as p24 antigen or nucleic acid (RNA or DNA) 0 to 180 days before or after an antibody test that had a negative or indeterminate result. Adapted from http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm.

The interplay between viral load and CD4 T-cell counts is often compared with that of a train heading toward a particular destination. If the destination is immune system destruction (and eventually death), then the T-cell count is the distance of the train from this destination, and the viral load (concentration of HIV RNA in plasma) is the speed of the train. As both higher speeds and shorter distances reach destinations faster, so does a high viral load and low T-cell count result in quicker onset of immune destruction (and death). Potent ART regimens decrease viral replication and dramatically alter the natural course of infection by prolonging the time to opportunistic infection and death.[41]

PHARMACOTHERAPY

Pharmacotherapy of HIV has been directed at inhibiting key areas of the HIV life cycle (Fig. 76-1 and animations found at http://biosingularity.wordpress.com/2007/03/04/3d--animation-of--hiv-replication/; **Table 76-2**).

Table 76-2

CDC MMWR Revised Surveillance Case Definition for HIV Infection—United States, 2014. Appendix Stage-3 Defining Opportunistic Illnesses in HIV Infection

Bacterial infections, multiple or recurrent[a]
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus
Cervical cancer, invasive[b]
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)
Encephalopathy attributed to HIV[c]
Herpes simplex: chronic ulcers (>1 month duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Mycobacterium tuberculosis of any site, pulmonary[b], disseminated or extrapulmonary
Mycobacterium, other species or unidentified species, disseminated or extrapulmonary
Pneumocystis jirovecii (previously known as *Pneumocystis carinii*) pneumonia
Pneumonia, recurrent[b]
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month
Wasting syndrome attributed to HIV[c]

[a]Only among children ages >6 years.

[b]Only among adults, adolescents, and children ages ≥6 years.

[c]Suggested diagnostic criteria for these illnesses, which might be particularly important for HIV encephalopathy and HIV wasting syndrome, are described in the following references: CDC. 1994 Revised classification system for human immunodeficiency virus infection in children age younger than 13 years. *MMWR*. 1994;43(RR-12):1–10; CDC. 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Recomm Rep*. 1992;41(RR-17):1–19. Adapted from http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6303a1.htm.

Nucleoside reverse transcriptase inhibitors (NRTIs) include abacavir (ABC), emtricitabine (FTC), lamivudine (3TC), and zidovudine (AZT). NRTIs currently only include tenofovir, which is available in two Food and Drug Administration (FDA)–approved prodrug formulations, tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). These agents inhibit this enzyme by incorporating false nucleic acids into the newly forming proviral DNA.[42] This results in an HIV DNA strand that cannot continue to elongate. Non-nucleoside reverse transcriptase inhibitors (NNRTIs; doravirine [DOR], efavirenz [EFV], etravirine [ETR], nevirapine [NVP], and rilpivirine [RPV]) inhibit reverse transcriptase by directly binding to the enzyme itself and prevent DNA transcription from RNA.[43]

Integrase strand transfer inhibitors (INSTIs; bictegravir [BIC], dolutegravir [DTG], elvitegravir [EVG], and raltegravir [RAL]) prevent the integrase enzyme from integrating HIV DNA into the immune cell's genome.[44]

Protease inhibitors (PIs; atazanavir [ATV], darunavir [DRV], and ritonavir [RTV]) directly bind to the catalytic site of HIV protease, inactivating the enzyme and preventing maturation of the HIV virion.[45],[46] Unlike reverse transcription, which occurs early in the course of the HIV life cycle, protease enzyme activity occurs late in virion development. As a result, inactivation of the protease enzyme inhibits viral replication in any infected cell regardless of the current stage of HIV replication within that cell. In contrast, reverse transcriptase inhibitors can protect newly infected cells from becoming latently infected cells before the formation and insertion of proviral DNA into the host cell's genetic material. However, these agents provide no benefit for those infected cells that are actively producing new strains of virus.

Pharmacokinetic (PK) enhancers are drugs that strongly inhibit CYP3A4, a liver enzyme responsible for metabolizing several PIs, NNRTIs, and INSTIs.[47] These agents are used with certain PIs and EVG to impede metabolism and increase serum drug concentrations in order to decrease dosing requirements. RTV, a PI itself, is now used primarily for its boosting effect rather than its anti-HIV activity. The newest PK enhancer, cobicistat (COBI), does not directly affect HIV replication.

Fusion inhibitors (enfuvirtide [T-20], fostemsavir, and ibalizumab [IBA]) prevent HIV and $CD4^+$ T cells from being pulled closer together after HIV binds to CD4 and CCR5 or CXCR-4 co-receptors. Enfuvirtide prevents fusion of the virus with the T cell by binding to a double coil–coil complex at the gp41–gp120–CD4 receptor area.[48] Because of the development of antiretroviral resistance, patients who have failed multiple ART regimens have few options to manage their disease.[49] In 2018, the FDA-approved IBA (Trogarzo), a novel monoclonal antibody dosed once every two weeks as an intravenous infusion in combination with other oral ART, for highly treatment-experienced patients who are failing on their current ART regimen.[50] Fostemsavir is a prodrug of the active moiety, temsavir, which is dosed orally twice daily in combination with other ART.[51] Maraviroc (MVC) is the only FDA-approved CCR5 co-receptor blocker, which prevents HIV from fully binding to cells and causing infection.[52]

With the development of newer, more potent ART regimens in the 2000s, researchers speculated about the possibility of completely eradicating HIV from an

infected patient (see video of challenges to curing HIV/AIDS at http://scienceofhiv.org/wp/?page_id=18). However, even in patients who have been virally suppressed for years on ART, HIV quickly re-emerges (within 2–3 weeks) in the blood (a phenomena known as viral rebound) following ART treatment interruption.[53] It is now widely recognized that the main barrier to eradication is HIV's ability to suppress its own replication and maintain this latent infection within extremely long-lived central memory T cells that have half-lives lasting more than 6 to 44 months. Given this half-life, complete suppression of HIV replication in all anatomical compartments for 60 years or more may be necessary to eradicate HIV in the presence of ART alone.[54–56] Another complicating factor is the potential for HIV to reside in sites that achieve low antiretroviral concentrations, thereby serving as sanctuaries for HIV replication (eg, central nervous system [CNS], testes). Once therapy is discontinued, these sites could theoretically release unaffected virions and repopulate the host.[57] As a result, research has shifted toward immune-based therapies that can identify and destroy HIV-infected cells, in addition to preventing HIV acquisition.[58],[59]

DIAGNOSIS

CASE 76-1

QUESTION 1: E.J. is a 27-year-old male who presents with fevers, night sweats, weight loss, and white patches in his mouth. He states that these symptoms have been present for the past 4 to 6 weeks. E.J. admits to intravenous drug use in the past; however, he states that he has been in recovery for 3 years. E.J. is diagnosed with thrush caused by *Candida albicans*. HIV infection is suspected and consent for an HIV test is obtained.

Why is HIV suspected and how is it confirmed?

In otherwise healthy, immunocompetent individuals, opportunistic infections, such as thrush, are rare because an intact cell-mediated immunity protects against infection. In immunosuppressed individuals, such as those infected with HIV, the immune system is significantly compromised and places patients at risk for opportunistic infections. Infections such as shingles (herpes zoster), tuberculosis, thrush, and recurrent candidal vaginal infections in an otherwise healthy person warrant further evaluation for the possibility of HIV infection. More advanced diseases, such as *P. jirovecii* pneumonia, *Mycobacterium avium* bacteremia, and cytomegalovirus retinitis infections, among others, generally occur in patients with severely depressed immune systems and strongly suggest HIV infection. This suggestion is especially true for those patients with risk factors for HIV infection.[3] Despite E.J.'s discontinuation of intravenous drugs, his prior use places him at risk for HIV infection. Given his social history and current clinical presentation, an HIV test is warranted.

Laboratory methods used to diagnose HIV infection rely on detecting antigens produced by HIV viral replication or antibodies produced by the host's immune response to HIV infection. After HIV infection, there is an initial eclipse period where no antigen or antibody laboratory markers can be consistently detected.[60] The first laboratory marker that can be reliably detected in the plasma after infection is HIV RNA by nucleic acid tests (NATs) ~10 days after infection, then p24 (a protein produced during viral replication) ~4 to 10 days after HIV RNA can be detected. The immune response to HIV infection is characterized first by the production of anti-HIV immunoglobulin (Ig)M proteins (10–13 days after HIV RNA can be detected) then IgG (18–38 days after HIV RNA can be detected). The period between infection with HIV and the ability to detect these antibodies is known as the seroconversion window, and the duration of this window can vary based on assay sensitivity or antibody type. Established infection is characterized by a fully developed IgG response.

Although early laboratory methods that utilized enzyme-linked immunosorbent assays (ELISA) and confirmatory Western blot to detect anti-HIV IgG antibodies were highly sensitive (>99%), the turnaround time for test results could be up to 1 to 2 weeks and the seroconversion window was 1 to 2 months long, making it difficult to diagnose early infections.[60] Third-generation HIV assays decreased the seroconversion window by including anti-HIV IgM.[60] Fourth-generation antigen/antibody combination assays further reduced this timeframe by testing for p24 antigen and anti-HIV-1 and 2 IgM/IgG. Fifth-generation assays further built on these advances and have allowed for fully automated procedures to differentiate among p24 antigen, HIV-1, and HIV-2 antibodies in 45 minutes, a process aligned with the Centers for Disease Control and Prevention's (CDC) 2018 quick reference guide for HIV testing algorithm in serum or plasma specimens.[61–63] Updated in January 2018—and to be used in conjunction with the 2014 recommendations—the quick reference states that unless there is reason to suspect very early infection, no further testing is required for a nonreactive antigen/antibody combination assay.[60,62] Specimen with reactive antigen/antibody results should be further tested with an immunoassay to differentiate HIV-1 and HIV-2 antibodies. NATs for HIV RNA should be used to confirm an indeterminate antibody differentiation immunoassay or a negative antigen/antibody tests in patients where there is reason to suspect very early infection.[60,62]

SURROGATE MARKER DATA

Although current guidelines recommend initiating therapeutic interventions for all HIV-infected persons ready to begin treatment, the severity of immune damage and potential for disease progression should still be assessed.[3] As stated previously, HIV predominantly infects and destroys T cells. The larger the viral load, the greater the risk for T-cell destruction and opportunistic infections. Therefore, quantitative measurements of E.J.'s HIV viral load and T-cell counts will assist in determining the

severity of infection, assessing the risk for disease progression, and providing a reference point (ie, baseline) for future therapeutic decisions.

Identification and measurement of T-lymphocyte subsets (eg, CD4, CD8) are based on flow cytometry readings of fluorescent-labeled monoclonal antibodies.[64] These values can vary widely on repeated laboratory evaluations, even in clinically stable patients. Patient samples can display up to 30% intralaboratory and interlaboratory variabilities.[3] Consequently, it is important to realize that assessment of T-cell measurements should always be interpreted as trends and not as individual values. Variability can also be minimized by using the same laboratory and by sampling patients at a consistent time of day.

The measurement of HIV viral load can be performed by one of three methods: reverse transcriptase–polymerase chain reaction (RT-PCR), branched-chain DNA assay, or nucleic acid sequence–based amplification.[65] Measurements using RT-PCR are obtained when viral RNA is amplified and counted. In contrast, branched-chain DNA amplifies and enumerates the signal from target probes attached to the viral RNA. Nucleic acid sequence–based amplification allows real-time, high-throughput amplification of viral RNA. All methods report HIV RNA in plasma as the number of copies per milliliter but have differing lower limits of quantitation.[3] It should be recognized that plasma viral RNA values measure the amount of free virus in the periphery and not the lymph nodes. Because viral concentrations are substantially greater in the lymph node, plasma measurements of HIV indirectly reflect spillover from replication in that compartment.[66,67]

Similar to CD4 counts, viral load measurements (copies/milliliter) can vary by as much as threefold (0.5 log) in either direction.[3] When obtaining a patient's baseline value, a number of issues must be considered. On initial infection with HIV, a burst of viremia occurs until the host's immune responses are able to control the infection. Consequently, viral load measurements obtained during the first 6 months of infection may not accurately reflect a true baseline value.[3] In addition, factors that activate the immune system, such as the development of a new opportunistic infection or immunizations,[68] can result in transient elevations of viral load measurements. In these situations, concentrations obtained within 4 weeks of the event may not accurately reflect the baseline viral load measurement.[3]

Some clinicians would recommend that at least two separate viral load measurements, which are obtained within 1 to 4 weeks of each other, be performed before making decisions regarding therapeutic options.[3] As with T-cell values, viral load measurements should be evaluated as trends.

In addition to quantifying the viral load, baseline resistance testing should be performed, using either genotypic or phenotypic testing, to guide the selection of the initial regimen. Resistance testing is recommended in most clinical situations before beginning treatment, because the rate of transmission of virus resistant to at least one drug (ie, transmitted drug resistance) has been noted in up to 10% to 17% of HIV-infected patients who have never been on ART in high-income countries (see Resistance, Viral Genotyping, Phenotyping, and Viral Fitness section, for further discussion).[3]

Case 76-1, Question 2: E.J.'s HIV-1/2 antigen/antibody combination immunoassay is reactive, and the antibody differentiation immunoassay detects HIV-1 antibodies. He is informed of his HIV status the next day at his follow-up examination. Before making any decisions regarding therapeutic options, what additional laboratory tests should be obtained?

E.J. should have a baseline T-cell count, viral load measurement, and viral genotype obtained. A complete blood count, electrolyte panel, renal and liver function tests, and hepatitis B and C serology should be performed. If specific therapies are being considered, such as ABC and MVC, specific testing is available to guide the appropriate use of these agents. HLA-B5701 screening is performed before starting a patient on ABC because of an increased risk for exhibiting a hypersensitivity reaction in patients positive for this allele. Co-receptor tropism assay is performed before initiating MVC to determine whether the patient has a virus that predominantly uses CCR5 receptors (versus ones that use primarily CXCR-4 receptors or ones that can use both).[3] These laboratory results help in selecting therapeutic options (see subsequent discussion) and establish baseline values in the event that problems are encountered in the future.

ANTIRETROVIRAL THERAPY

Case 76-1, Question 3: E.J.'s T-cell count and viral load measurement return at 225 cells/μL and 145,000 copies/mL (by RT-PCR assay), respectively. Should ART be initiated?

ART should be offered to all patients who are willing and able to commit to lifelong treatment after an in-depth discussion of the benefits and risks of ART and the importance of adherence. This recommendation is based on the results of two large randomized clinical trials (START; The Strategic Timing of AntiRetroviral Treatment and the TEMPRANO ARNS 12136 Study). These trials investigated the risks and benefits of initiating ART at a CD4 count >500 cell/μL versus delaying until the CD4 count declined to >350 cell/μL. A significant increase in morbidity and mortality was observed when ART was delayed.[3] In further support of starting ART regardless of baseline CD4 count, the guidelines recognize the benefits of initiating ART for HIV prevention and support initiating ART to prevent perinatal and heterosexual transmission (AI evidence rating) or other transmission risks (AIII evidence rating). Understanding logistical concerns related to the linkage of care between initial HIV diagnosis and ART prescribing, there are recommendations regarding rapid ART initiation on the same day of HIV diagnosis. This is intended to enhance the uptake of ART and promote the engagement in clinical care to achieve viral suppression, which has been demonstrated in numerous studies, both in the United States and in resource-limited settings.[69–72] Certain clinical situations favor urgent initiation of ART include pregnancy: AIDS-defining condition such as an opportunistic infection and acute/early HIV infection.[3] In patients who are asymptomatic, assessment of the

patient's surrogate marker data (T-cell count, viral load measurements), concurrent medical conditions, medication adherence history (if any), and motivation to initiate therapy are necessary.

In otherwise healthy, immunocompetent persons, T-cell measurements are >1200 cells/μL. In patients who have been chronically infected with HIV, significant T-cell destruction occurs. When T-cell counts fall to <500 cells/μL, patients are at increased risk for opportunistic infections. The risk of disease progression is closely tied to CD4 cell counts, with low CD4 counts (<200 cells/μL) predicting both short-term and long-term risk of disease progression.[73–75] High viral load (>100,000 copies/mL), increasing age, acquisition of infection through intravenous drug use, and a previous AIDS diagnosis also increase the risk of disease progression in observational cohorts.

The decision to initiate ART should not be taken lightly. ART regimens may improve the quality and duration of a patient's life, but they are not without risks. Patients should be counseled that ART should be continued indefinitely without interruption to improve and preserve the immune system. For some patients, this may be a difficult realization, particularly if the patient is relatively healthy. In addition, the risk of adverse events/toxicities and the costs of ART should be considered before beginning treatment. These guidelines, therefore, should be used to initiate discussions with the patient regarding the risks and benefits of therapy. It is critical for practitioners to talk openly with patients about their fears and concerns and make an assessment about their motivation to initiate therapy and ability to adhere to a lifelong regimen, and the U.S. Department of Health and Human Services (DHHS) guidelines support this discussion.[3] The patient should always make the final decision after careful discussions with the practitioner.

E.J. has a number of significant risk factors for disease progression. He is clinically symptomatic with oral thrush and nonspecific constitutional symptoms (eg, fevers, night sweats, and weight loss). His surrogate marker data place him at risk for greater disease progression (T-cell count <500 cells/μL and viral load >100,000 copies/mL). Based on these values, E.J. should be counseled on his risk of disease progression, potential adverse events associated with both starting and deferring treatment, and his willingness to adhere to a regimen.

Before developing a patient-specific regimen, it is important to recognize the benefits and limitations of ART and identify obtainable and realistic goals.

Case 76-1, Question 4: After careful discussions, E.J. agrees to initiate ART. What should be the goals of therapy? What other factors or information should be considered in selecting an appropriate regimen?

Goals of Therapy

GOAL 1: MAXIMALLY AND DURABLY SUPPRESS VIRAL LOAD

Maximal viral suppression often results in significant increases in T-cell counts and improved clinical outcomes. Based on our understanding of viral pathogenesis, this finding is not surprising. Lower amounts of replicating virus result in decreased risk for T-cell infection and destruction and, subsequently, a more intact immune response. Therefore, therapy should suppress viral replication to undetectable levels in the plasma (>50 copies/mL), for as long as possible.[3–5] The development of new ART with improved potency, higher genetic barrier to resistance, low adverse event profiles, and more convenient dosing regimens (including once-daily single tablet regimens) makes viral suppression a reasonable goal in most patients, even those who previously have received multiple suboptimal regimens or failed therapy. In the treatment-experienced patient, however, special care must be given to designing a regimen that will suppress viral load, yet not contribute to the development of drug resistance that limits future treatment options. Consultation with an expert in ART resistance patterns is critical to designing a salvage regimen in such patients.

The development of drug resistance is also a consideration in the selection of regimens for patients who have not previously used ART (ART naive). In any given viral population, the potential exists for a spontaneous mutation to occur, which results in a resistant isolate. The larger the population, the greater the risk for mutations. HIV replication is a highly error-prone process, especially with the reverse transcriptase enzyme. Given the high rate of viral replication, the potential exists for the daily production of thousands of replication-competent viral mutations to each and every site on the HIV genome (~10,000 nucleotides in length).[4,35] Under selective pressures from inadequate ART, spontaneously produced isolates with reduced susceptibility to the given regimen eventually flourish and repopulate the host. This fact is of particular concern, given the potential for cross-resistance between ART (see the following discussion of resistance). Therefore, the use of a regimen that fully suppresses viral replication reduces the potential for mutations and the development of cross-resistance.

Although >30 FDA-approved ART agents are currently available to use in combination therapies, many of these agents display similar resistance profiles. Developing resistance to one or more agents in a given regimen may result in the loss of activity to other agents with similar resistance profiles (ie, cross-resistance).[4] Whether drug resistance develops is determined by the genetic barrier associated with the individual antiretroviral drugs. Some drugs have low genetic barriers; that is, only one or two critical changes in the virus are necessary for resistance to occur. An example of a class of agents with a low genetic barrier is the NNRTIs. Although a number of individual point mutations in the viral genome can confer the loss of activity for the first-generation NNRTIs (EFV and NVP), second-generation NNRTIs (DOR, ETR, and RPV) exhibit improved barriers to resistance compared to these first-generation agents. In contrast, the PIs have a wide genetic barrier, which requires multiple changes to the viral genome to incur resistance.[4]

It should be recognized, however, that just because an agent has a low genetic barrier does not mean it is virologically inferior or less potent. Potent regimens containing NNRTIs are highly effective and provide durable treatment responses. The

potency of the entire regimen is critical to determining whether drug resistance develops.[3] If viral replication is suppressed, the development of resistance will be minimal. When viral replication does occur, the greater the replication, the greater the risk for development of resistance. In situations in which viral replication does occur, inclusion of a drug with a low genetic barrier in the ART regimen may be risky and could result in the loss of activity of the drug, the development of cross-resistance to other drugs, or both. As a result, an ART regimen should be selected that has a high likelihood of suppressing viral replication and to which the patient will strictly adhere.

GOAL 2: PRESERVE AND STRENGTHEN THE IMMUNE SYSTEM

Decreasing viral replication usually leads to increased CD4 cell counts, which strengthens and preserves the immune system. With increased cell counts, patients are at lower risk for exhibiting opportunistic infections and death. With newer and improved regimens, strengthening and preserving the immune system may be possible even in treatment-experienced patients, although drug regimens must be designed carefully to prevent developing further resistance. Full immune reconstitution may not be possible if the CD4 cell count is low for a long period of time; however, it is reasonable to try and restore immune function as fully as possible. Despite advances in drug therapy, it is important to remember that HIV remains an incurable condition.

GOAL 3: LIMIT DRUG ADVERSE EVENTS, PROMOTE ADHERENCE, AND IMPROVE QUALITY OF LIFE

Treatment with combination therapy has been shown to be highly effective in suppressing HIV replication and improving survival among PLWH. Lifelong adherence to an ART is required and can be a complex and difficult task, although advances in co-formulation of drug products have simplified HIV treatment considerably. Several once-daily regimens and single tablet regimens are recommended as first-line therapy (**Tables 76-2** and **76-3**), and long-acting injectable therapies will likely be available soon. The patient's ability to adhere to therapy may, however, still be the difference between a regimen that fails and one that results in a clinical benefit. The first regimen generally provides the best chance for treatment success. Although newer ART tend to exhibit better adverse event profiles compared to the early ART, adverse events can still make tolerating these regimens difficult and affect drug adherence and response to therapy. Changes in body composition (known as lipodystrophy), increases in lipids and triglycerides, decreases in bone mineral density, increased risks for cardiac disease, and the development of lactic acidosis are serious concerns.[3]

Table 76-3

Characteristics of Antiretroviral Agents for the Treatment of Adult Human Immunodeficiency Virus Infection

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Nucleoside Reverse Transcriptase Inhibitors			
Abacavir (ABC) **Ziagen** *Preparations* Tablets: 300 mg Oral solution: 20 mg/mL Epzicom: ABC 600 mg + 3TC 300 mg Trizivir: ABC 300 mg + ZDV 300 mg + 3TC 150 mg Triumeq: ABC 600 mg + 3TC 300 mg + DTG 50 mg	300 mg every 12 hours, or 600 mg daily Epzicom: one tablet daily Trizivir: one tablet bid Triumeq: one tablet daily	*Oral bioavailability*: 83% *Serum* $t_{1/2}$: 1.5 hours *Intracellular* $t_{1/2}$: 12–26 hours *Elimination*: alcohol dehydrogenase and glucuronyltransferase; 82% renal elimination of metabolites	Can be administered without regard to meals Alcohol raises abacavir exposure by 41% HLA testing required before administration
Lamivudine (3TC) **Epivir** *Preparations* Tablets: 150, 300 mg Solution: 10 mg/mL Combivir: 3TC 150 mg + ZDV 300 mg Epzicom: 3TC 300 mg + ABC 600 mg Trizivir: 3TC 150 mg + ZDV 300 mg + ABC 300 mg Triumeq: ABC 600 mg + 3TC 300 mg + DTG 50 mg	150 mg PO bid or 300 mg PO daily Combivir: one tablet bid Epzicom: one tablet bid Trizivir: one tablet bid Triumeq: one tablet daily	*Oral bioavailability*: 86% *Serum* $t_{1/2}$: 5–7 hours *Intracellular* $t_{1/2}$: 18–22 hours *Elimination*: 70% unchanged in urine	Can be administered without regard to meals
Emtricitabine (FTC) **Emtriva** *Preparations* Capsules: 200 mg Oral solution: 10 mg/mL Truvada: FTC 200 mg + TDF 300 mg Atripla: FTC 200 mg + TDF 300 mg + EFV 600 mg Complera: FTC 200 mg + RPV 25 mg + TDF 300 mg Stribild: FTC 200 mg + EVG/c 150/150 mg + TDF 300 mg Descovy: FTC 200 mg + TAF 300 mg Odefsey: FTC 200 mg + RPV 25 mg + TAF 25 mg Genvoya: FTC 200 mg + EVG/c 150/150 mg + TAF 10 mg	200 mg daily for patients with calculated CrCl >50 mL/minute Dose needs to be adjusted for renal dysfunction: CrCl 30–49 mL/minute: 200 mg every 48 hours CrCl 15–29 mL/minute: 200 mg every 72 hours CrCl >15 mL/minute: 200 mg every 96 hours Truvada: one tablet daily. Not for patients with CrCl >30 mL/minute Atripla: one tablet daily. Not for patients with CrCl >50 mL/minute Complera: one tablet daily Stribild: one tablet daily. Not for patients with CrCl >70 mL/minute Stribild: one tablet daily. Not for patients with CrCl >70 mL/minute	*Oral bioavailability*: 93% *Serum* $t_{1/2}$: 10 hours *Intracellular* $t_{1/2}$: >20 hours *Elimination*: 86% recovered in urine	Can be administered without regard to meals
Tenofovir Disoproxil Fumarate (TDF) **Viread** *Preparations* Tablets: 150, 200, 250, 300 mg Oral powder: 40 mg/g Truvada: TDF 300 mg + FTC 200 mg Atripla: TDF 300 mg + FTC 200 mg + EFV 600 mg Complera: FTC 200 mg + RPV 25 mg + TDF 300 mg Stribild: FTC 200 mg + EVG/c 150/150 mg + TDF 300 mg	300 mg daily for patients with CrCl >60 mL/minute Truvada: one tablet daily. Not for patients with CrCl >30 mL/minute Atripla: one tablet daily. Not for patients with CrCl >50 mL/minute Complera: one tablet daily Stribild: one tablet daily. Not for patients with CrCl >70 mL/minute	*Oral bioavailability*: 25% fasting; 39% with high-fat meal *Serum* $t_{1/2}$: 17 hours *Intracellular* $t_{1/2}$: >60 hours *Elimination:* primarily by glomerular filtration and active tubular secretion	Can be administered without regard to meals

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Nonpreferred Nucleoside Reverse Transcriptase Inhibitors			
Tenofovir alafenamide (TAF) *Preparations* Descovy: TAF 25 mg + FTC 200 mg Odefsey: FTC 200 mg + RPV 25 mg + TAF 25 mg Genvoya: FTC 200 mg + EVG/c 150/150 mg + TAF 10 mg	25 mg for patients with CrCl >30 mL/minute Descovy: one tablet daily Odefsey: one tablet daily Genvoya: one tablet daily	*Oral bioavailability:* 40% *Serum* $t_{1/2}$: 0.51 hours *Intracellular* $t_{1/2}$: 150–180 hours *Elimination*: primarily by glomerular filtration and active tubular secretion	Can be administered without regard to meals
Zidovudine (ZDV) **Retrovir (R)** *Preparations* Oral solution: 10 mg/mL Capsule: 100 mg Tablet: 300 mg IV solution: 10 mg/mL Combivir: ZDV 300 mg + 3TC 150 mg Trizivir: ZDV 300 mg + 3TC 150 mg + ABC 300 mg	300 mg bid or 200 mg tid Combivir (R) or Trizivir (R): one tablet bid	*Oral bioavailability*: 60% *Serum* $t_{1/2}$: 1.1 hours *Intracellular* $t_{1/2}$: 3 hours *Elimination*: hepatic glucuronidation; renal excretion of glucuronide metabolite	Can be administered without regard to meals (manufacturer recommends administration 30 minutes before or 1 hour after a meal.)
Didanosine (ddI) **Videx** *Preparations* Videx EC (R): 125, 200, 250, 400 mg capsule Pediatric powder for oral solution (when reconstituted as solution containing antacid): 10 mg/mL Generic ddI enteric-coated capsule also available	>60 kg: 400 mg daily (with TDF, use 250 mg daily) >60 kg: 250 mg daily (with TDF, use 200 mg daily)	*Oral bioavailability*: 30%–40% *Serum* $t_{1/2}$: 1.6 hours *Intracellular* $t_{1/2}$: 25–40 hours *Elimination:* renal excretion ~50%	Food decreases absorption (decreases 55%); administer ddI on empty stomach (1 hour before or 2 hours after meal) Separate ATV and TPV/r administration by at least 2 hours.
Stavudine (d4T) **Zerit** *Preparations* Solution: 1 mg/mL Capsules: 15, 20, 30, 40 mg	>60 kg: 40 mg bid >60 kg: 30 mg bid Sustained release: >60 kg use 100 mg daily; >60 kg use 75 mg daily	*Oral bioavailability*: 86% *Serum* $t_{1/2}$: 1.0 hour *Intracellular* $t_{1/2}$: 3.5 hours *Elimination*: renal excretion ~50%	Can be administered without regard to meals
Non-Nucleoside Reverse Transcriptase Inhibitorsa			
Rilpivirine (RPV) **Edurant** *Preparations* Tablets: 25 mg Complera: RPV 25 mg + TDF 300 mg + FTC 200 mg Odefsey: RPV 25 mg + TAF 25 mg + FTC 200 mg	25 mg daily Complera: one tablet daily	*Oral bioavailability*: not established *Serum* $t_{1/2}$: ~50 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism primarily by CYP3A4 with 85% fecal excretion	Take with moderate-to-high calorie meal (increases absorption 40%).
Efavirenz (EFV) **Sustiva®** *Preparations* Capsules: 50, 100, 200 mg Tablets: 600 mg Atripla: EFV 600 mg + TDF 300 mg + FTC 200 mg	600 mg at bedtime Atripla one tablet at bedtime. Not for patients with CrCl >50 mL/minute	*Oral bioavailability*: ~60%–70% *Serum* $t_{1/2}$: 40–55 hours *Intracellular* $t_{1/2}$: unknown *Elimination:* hepatically metabolized by CYP2B6 and CYP3A4 (also CYP3A4 mixed inhibitor/inducer)	Avoid taking with high-fat meals, concentrations increases 50% (increased risk for CNS toxicity).
Etravirine (ETV) **Intelence** *Preparations* Tablets: 100, 200 mg	200 mg bid	*Oral bioavailability*: unknown *Serum* $t_{1/2}$: 40 ± 20 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatically metabolized by CYP3A4, CYP2C9, CYP2C19 (also 3A4 inducer, 2C9 and 2C19 inhibitors)	Take after a meal.

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Nonpreferred Non-Nucleoside Reverse Transcriptase Inhibitors[a]			
Nevirapine (NVP) **Viramune** *Preparations* Suspension: 50 mg/5 mL Tablets: 200 mg	200 mg PO daily × 14 days, then 200 mg PO bid	*Oral bioavailability*: >90% *Serum* $t_{1/2}$: 25–30 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: metabolized by CYP2B6 and CYP3A4 (also a CYP3A4 inducer) with 80% excreted in urine as the glucuronide metabolite	Can be administered without regard to meals
Protease Inhibitors			
Darunavir (DRV) **Prezista** *Preparations* Tablet: 75, 150, 600, 800 mg Suspension: 100 mg/ml Prezcobix®: DRV 800 mg + COBI 150 mg	DRV 800 mg + RTV 100 mg daily In patients with ≥1 DRV resistance mutations: DRV 600 mg + RTV 100 mg bid Prezcobix®: one tablet daily	*Oral bioavailability*: 37% alone, 82% with RTV *Serum* $t_{1/2}$: 15 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (inhibitor)	Food increases C_{max} and AUC by 30%: administer with food.
Atazanavir (ATV) **Reyataz** *Preparations* Capsules: 100, 150, 200, 300 mg Evotaz®: ATV 300 mg + COBI 150 mg	400 mg daily Atazanavir/RTV: 300/100 daily Evotaz®: one tablet daily	*Oral bioavailability*: 60%–70% *Serum* $t_{1/2}$: 6–7 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (modest inhibitor)	Take with food, and avoid acid suppressing agents (which prevent ATV solubility and absorption).
Lopinavir (LPV)/ritonavir (RTV) **Kaletra** *Preparations* Tablet: LPV 200 mg + RTV 50 mg Solution: LPV 80 mg+ RTV 20 mg per mL	Two tablets or 5 mL bid or Four tablets or 10 mL daily (recommended for treatment-naive patients only)	*Oral bioavailability*: not determined *Serum* $t_{1/2}$: 5–6 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (inhibitor)	Take with food (increases AUC by 48%). Tablet stable at room temperature.
Nonpreferred Protease Inhibitors			
Indinavir (IDV) **Crixivan** *Preparations* Capsule: 200, 333, 400 mg	800 mg every 8 hours (bid dosing ineffective when sole protease inhibitor) IDV/RTV: IDV 800 mg + 100 mg or 200 mg RTV bid	*Oral bioavailability*: 65% *Serum* $t_{1/2}$: 1.5–2 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatically metabolized via CYP3A4 (also inhibitor of CYP3A4)	Must be taken on empty stomach (1 hour before or 2 hours after a meal); may be taken with skim milk or low-fat meal Adequate hydration necessary (at least 1.5 L/24 hours of liquid) to minimize risk of nephrolithiasis
Nelfinavir (NFV) **Viracept** *Preparations* Powder for oral suspension: 50 mg per one level scoop (200 mg per one level teaspoon) Tablets: 250 and 625 mg	750 mg tid or 1250 mg bid	*Oral bioavailability*: 20%–80% *Serum* $t_{1/2}$: 3.5–5 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4	Administer with meal or light snack (exposure increased two- to threefold).
Saquinavir (SQV) **Invirase** (hard gel capsules) *Preparations* Hard gel capsule: 200 mg Tablets: 500 mg	Unboosted saquinavir not recommended Saquinavir/ritonavir: 1000/100 bid; 1600/100 daily under investigation	*Oral bioavailability*: 4% (as the sole PI) *Serum* $t_{1/2}$: 1–2 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (inhibitor)	Take within 2 hours of a meal and take with RTV.

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Fosamprenavir (FPV) **Lexiva** Tablet: 700 mg	In ARV-naive patients: FPV 1400 mg bid or FPV 1400 mg + RTV 200 mg daily or FPV 700 mg + RTV 100 mg bid In PI-experienced patients: FPV 700 mg + RTV 100 mg bid	*Oral bioavailability*: not determined *Serum* $t_{1/2}$: 7.1–10.6 hours (APV) *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (inhibitor)	Can be taken without regard to meals but should not be taken with high-fat meals
Tipranavir (TPV) **Aptivus®** Capsules: 250 mg	TPV 500 mg + RTV 200 mg bid DO NOT USE WITHOUT RTV	*Oral bioavailability*: not determined *Serum* $t_{1/2}$: 6 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism via CYP3A4 (inhibitor and inducer)	Administer with food to increase bioavailability.
Entry Inhibitors			
Enfuvirtide (T-20) Fuzeon	90 mg SC bid in upper arm, thigh, or abdomen	*Oral bioavailability*: 84.3% compared with IV *Serum* $t_{1/2}$: 3.8 hours *Intracellular* $t_{1/2}$: not applicable *Elimination*: nonrenal, nonhepatic	Reconstitute with 1.1 mL sterile water for injection; gently tap vial for 10 seconds and then roll gently between hands to avoid foaming and ensure all drug is off vial walls. After reconstitution, use immediately or refrigerate for 24 hours. Refrigerated T-20 should be brought to room temperature before injection.
Chemokine Receptor Antagonists (CCR5)			
Maraviroc (MVC) **Selzentry** *Preparations* Tablet: 150, 300 mg	300 mg bid (with all NRTIs, NVP, TPV, ENF), 150 mg bid with CYP3A inhibitors (with or without a CYP3A inducer) including protease inhibitors (except tipranavir/ritonavir), delavirdine, ketoconazole, itraconazole, clarithromycin, and other strong CYP3A inhibitors (eg, nefazodone, telithromycin) 600 mg bid with CYP3A inducers (without a strong CYP3A inhibitor) including Efavirenz, etravirine (TMC125), rifampin, carbamazepine, phenobarbital, and phenytoin	*Oral bioavailability*: ~33% *Serum* $t_{1/2}$: 14–18 hours *Elimination*: hepatic metabolism by CYP3A; 20% recovered in urine, 76% recovered in feces	Can be administered without regard to meals (high-fat meal decreases C_{max} and AUC by ~30%) Trofile assay must be performed before administration.
Integrase Inhibitors			
Dolutegravir (DTG) **Tivicay** *Preparations* Tablet: 50 mg Triumeq: DTG 50 mg + ABC 600 mg + 3TC 300 mg	50 mg once daily 50 mg bid when coadministered with EFV, FPV/r, TPV/r, or rifampin 50 mg bid when INSTI mutations present Triumeq: one tablet daily	*Oral bioavailability*: unknown *Serum* $t_{1/2}$: ~14 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism by UGT1A1 (major) CYP3A4 (minor); 31% recovered in urine, 53% recovered in feces	Increased serum creatinine because of inhibition of tubular secretion not decreased renal glomerular filtration. Mean (range) increase from baseline = 0.15 (−0.32 to 0.65) mg/dL

Drug	Dose	Pharmacokinetic Parameters	Administration Considerations
Elvitegravir (EVG) **Vitekta** *Preparations* Tablet: 85, 150 mg Stribild: EVG 150 mg + COBI 150 mg + FTC 200 mg + TDF 300 mg Genvoya: EVG 150 mg + COBI 150 mg + FTC 200 mg + TAF 10 mg	85 mg once daily if coadministered with ATV/r or LPV/r 150 mg once daily if coadministered with DRV/r 600/100 mg bid, FPV/r 700/100 mg bid, or TPV/r 500/200 mg bid 50 mg bid when INSTI mutations present Stribild: one tablet daily	*Oral bioavailability*: not established *Serum* $t_{1/2}$: 9 hours when administered with RTV *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism by CYP3A, and UGT1A1/3; 6.7% recovered in urine, 94.8% recovered in feces	Vitekta must be administered with ritonavir unboosted. EVG is not recommended. Take with food.
Raltegravir (RAL) **Isentress®** *Preparations* Tablet: 400 mg, 1200 mg HD Chewable tablet: 25, 100 mg Single packet for oral suspension: 100 mg	400 mg bid or 1200 mg (HD) daily	*Oral bioavailability*: not established *Serum* $t_{1/2}$: 9 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: hepatic metabolism by UGT1A1 glucuronidation; 32% recovered in urine, 51% recovered in feces	Can be administered without regard to meals (high-fat meal decreases C_{max} by ~34% and increases AUC by ~19%)
Pharmacokinetic Enhancers			
Ritonavir (RTV) **Norvir®** *Preparations* Oral solution: 80 mg/mL Capsules: 100 mg Tablets: 100 mg	RTV is a PI currently used as a pharmacokinetic enhancer for other PIs and EVG, using 100–400 mg/day in one to two divided doses	*Oral bioavailability*: Not determined *Serum* $t_{1/2}$: 3–5 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: extensive hepatic metabolism via CYP3A4 (also potent CYP3A4 inhibitor and mixed inhibitor/inducer of other isozymes)	Take with food if possible to improve tolerability Dose should be titrated upward to minimize gastrointestinal adverse events Refrigerate capsules but not liquid or tablets Solution contains 43% alcohol.
Tybost **(COBI)** **Cobicistat** *Preparations* Tablets: 150 mg Stribild: EVG 150 mg + COBI 150 mg + FTC 200 mg + TDF 300 mg Prezcobix®: DRV 800 mg + COBI 1 50 mg Evotaz®: ATV 300 mg + COBI 150 mg	150 mg daily when coadministered with ATV 300 mg daily 150 mg daily when coadministered with DRV 800 mg daily Stribild: one tablet daily. Not for patients with CrCl >70 mL/minute Prezcobix®: one tablet daily Evotaz®: one tablet daily	*Oral bioavailability*: Not determined *Serum* $t_{1/2}$: 3–5 hours *Intracellular* $t_{1/2}$: unknown *Elimination*: extensive hepatic metabolism via CYP3A4 (also potent CYP3A4 inhibitor and mixed inhibitor/inducer of other isozymes) 8.2% recovered in urine, 86.2% recovered in feces	Not interchangeable with RTV Increased serum creatinine because of inhibition of tubular secretion not decreased renal glomerular filtration. Monitor for renal safety if increased from baseline >0.4 mg/dL.

ABC, abacavir; ARV, antiretroviral; ATV, atazanavir; AUC, area under the curve; bid, twice daily; CNS, central nervous system; COBI, cobicistat; CrCl, creatinine clearance; ddI, didanosine; d4T, stavudine; DLV, delavirdine; DRV, darunavir; DTG, dolutegravir; EFV, efavirenz; ENF, enfuvirtide; ETV, etravirine; EVG, elvitegravir; FPV, fosamprenavir; FTC, emtricitabine; HLA, human leukocyte antigen; IDV, indinavir; IV, intravenous; LPV, lopinavir; MVC, maraviroc; NFV, nelfinavir; NNRTI, non-nucleoside reverse transcriptase inhibitor; NRTIs, nucleoside reverse transcriptase inhibitors; NVP, nevirapine; PI, protein inhibitor; PO, orally; qid, four times daily; RAL, raltegravir; RPV, rilpivirine; RTV, ritonavir; SC, subcutaneously; SQV, saquinavir; 3TC, lamivudine; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate; tid, three times daily; TPV, tipranavir; TPV/r, tipranavir/ritonavir; T-20, enfuvirtide; ZDV, zidovudine.

[a]In clinical trials, the NNRTIs were discontinued because of rash in 7% of patients taking nevirapine, 4.3% of patients taking delavirdine, and 1.7% of patients taking efavirenz. Rare cases of Stevens–Johnson syndrome have been reported with all three NNRTIs.

Antiretroviral drugs for treatment and prevention of HIV infection in adults: 2020 recommendations of the International Antiviral Society-USA Panel. *JAMA*. 2020;324(16):1651–1669. doi:10.1001/jama.2020.17025.

Limit adverse events

Although new ART offers marked improvement over early generation agents' toxicity profiles, lifelong ART is not without risk. Historically, metabolic complications from older ART include abnormal distribution of body fat, lipid abnormalities (eg, hypercholesterolemia, hypertriglyceridemia, increases in low-density lipoprotein [LDL] and decreases in high-density lipoprotein [HDL]), and new-onset diabetes.[76–78] Concerning modern ART, there are risks related to cardiovascular outcomes (ABC and PIs), renal and bone mineral density concerns (tenofovir-based regimens), and weight gain (INSTIs), which are discussed below.

With more modern ART, cardiovascular risks exist. For instance, ABC has been associated with myocardial infarctions after adjustment for known risk factors and the Framingham risk scores.[79] PIs are also implicated in cardiovascular risk. In a large international prospective multicohort study, it was noted that the cumulative use of boosted DRV—and not boosted ATV, was associated with the risk of cardiovascular disease after adjustment for factors, including those already at high risk of cardiovascular disease.[80]

TAF, a novel formulation of tenofovir, is associated with improved long-term bone and renal outcomes compared to TDF in patients initiating therapy, and this has been seen in a double-blind, multicenter, noninferiority trial between FTC/TAF and FTC/TDF after 48 and 96 weeks of follow-up.[81] However, with the availability of generic TDF (FDA approved in June 2017), balancing lower cost versus improved safety will be an important consideration for clinicians in selecting a tenofovir-based regimen, especially considering that both formulations are equally recommended by the guidelines.

The INSTI-based regimens, which are first-line ART, have been associated with weight gain.[82] Additionally, the weight gain is differentially based on the specific INSTI. In a large observational study, the adjusted average weight gain was higher after 6 and 18 months for RAL (3.0 and 3.4 kg, respectively) but not for EVG (0.6 and 0.5 kg, respectively).[83] The majority of the reports of weight gain have been related to DTG, which has received more scrutiny, particularly in lower-income countries. On average, the increase in body weight is ~3 to 4 kg but can be as high as 6.0 kg after 18 months.[83] Furthermore, in the New Antiretroviral and Monitoring Strategies in HIV-infected Adults in Low-Income Countries (NASMAL) and the ADVANCE studies, participants were randomized to a DTG-based regimens in both with findings supporting a 10% increase in body weight and statistically significantly higher weight gain compared to control NNRTI-based ART.[84],[85] Lastly, the weight gain associated with BIC is comparable to that seen in DTG in noninferiority trials compared to DTG-based regimens with median weight gain of 7.71 pounds (3.5 kg) after 96 weeks.[86],[87]

Promote adherence

Although the exact degree of adherence required for clinical success is currently unknown and varies by antiretroviral class, taking 90% to 95% of prescribed doses is generally believed to be necessary to prevent the development of resistance. Data

from studies evaluating adherence among HIV-infected patients indicate that ~62% of patients take ≥90% of the prescribed doses of ART.[88] Although it is important to note that adherence patterns vary widely based on patient-specific factors. Poor adherence is multifactorial and related to behavioral, structural, and psychosocial concerns.[89–91] Factors associated with poor adherence include (a) patient's social situation and clinical condition, (b) prescribed regimen (once-daily regimens vs multiple pills per day), and (c) quality of the patient–provider relationship.

To better address the complex, multidimensional, patient-specific structures that can influence adherence behavior and retention in care, the DHHS HIV treatment guidelines recommend that clinics adopt a multidisciplinary team approach that provides access to trustworthy case managers, pharmacists, social workers, nurses, psychiatric care providers, and so on.[3] Additionally, before selecting an ART regimen, clinicians should provide adherence-related education (including information regarding why adherence is important) and involve the patient in the ART selection process. Selecting a treatment plan that the patient can (a) understand and (b) commit to for the long term is critical for fostering lifelong adherence. Thus, considering the patient's daily schedule and their ability to comply with antiretroviral-specific requirements (ie, food requirements, drug interactions) is important. For example, DTG should be administered 2 hours before polyvalent cation supplements. When DTG and iron-containing supplements are administered simultaneously under fasting conditions, DTG exposure decreases by 54%. For this reason, it is recommended to administer DTG together with food or to administer DTG at least 2 hours before or at least 6 hours after the polyvalent-containing supplement. Involving patients in the selection of their antiretroviral regimen maximizes the possibility of selecting a regimen that is least burdensome to their daily routine and helps to reduce certain barriers that lead to poor adherence. After the ART regimen has been selected and treatment is initiated, quickly identifying patients who are struggling with adherence (via patient self-report, pharmacy records, pill counts, etc), identifying their specific barriers to adherence (eg, pill fatigue, high co-pays, forgetfulness) and employing targeted interventions to improve adherence are essential. A recent technological strategy is the utilization of mobile applications (apps), which focuses on consistent daily alarms and text messaging reminders. Although recent meta-analyses of adherence apps and text messages reminders have indicated mixed efficacy results, cellular phones that support apps are now more globally available and may more readily promote adherence in clinical trials.[92,93] Of note, the CDC has promoted a free mobile app called Ever Dose Every Day (E2D2; available at https://npin.cdc.gov/pages/new-resource-every-dose-every-day-e2d2-toolkit-and-app). Examples of other specific strategies to improve adherence can be found in Table 16 (https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/AA_Tables.pdf) of the 2019 DHHS HIV treatment guidelines.[3]

Finally, considering the importance of adherence in suppressing viral replication, long-acting (LA) injectables are a promising option for HIV treatment that offer less burdensome dosing compared to daily oral medications. The FDA recently approved

the first LA injectable regimen consisting of the novel INSTI cabotegravir (CAB) and RPV. LA-CAB/RPV is indicated for patients currently suppressed (HIV RNA <50 copies/mL) on an ART regimen with no history of treatment failure and no known or suspected resistance to either agent. As of this writing, patients should be prescribed a month-long course of oral CAB/RPV prior to receiving the injectable formulation to ensure they are well-tolerated. However, as safety data accumulates, forthcoming guidelines are anticipated to omit the recommendation or an oral lead-in period. LA-CAB/RPV was approved for HIV treatment on the basis of three phase III randomized clinical trials. The ATLAS study randomized virologically suppressed patients 1:1 to either continue current oral ART or to switch to monthly intramuscular injections of LA-CAB/RPV following a 4-week oral lead-in period consisting of CAB 30 mg plus RPV 25 mg once daily with food to assess safety and side effects.[94] At 48 weeks, LA-CAB/RPV was noninferior with 92.5% of participants maintaining viral suppression.[94] Similarly, in the FLAIR study, participants received DTG/ABC/3TC for 20 weeks to achieve virologic suppression, then were randomized 1:1 to receive monthly intramuscular injections of LA-CAB/RPV following a 4-week oral CAB/RPV lead-in or to continue oral DTG/ABC/3TC.[95] At 96 weeks, LA-CAB/RPV was noninferior with 87% of participants maintaining viral suppression in the per-protocol analyses.[95] Finally, the initial LATTE-2 study examined every 4- and 8-week administrations of LA-CAB/RPV following oral CAB/RPV lead-in. The authors noted that at week 96, 87% and 94%, respectively, maintained viral suppression, which were both as effective as oral treatment with conventional ART.[96] In the study, the every 4-week administration group had a lower rate of virologic nonresponse (defined as HIV-1 RNA ≥50 copies/mL per the FDA Snapshot Algorithm) than the every 8-week group (0% and 4%, respectively).[96] This led to the selection of the 4-week dosing regimen in the ATLAS and FLAIR trials. Future approval decision-making may invite every 8-week LA-CAB/RPV administration to the armamentarium.

GOAL 4: PREVENT HUMAN IMMUNODEFICIENCY VIRUS–RELATED MORBIDITY AND MORTALITY

By successfully treating HIV (suppressing viral load and restoring immune function), patients are at decreased risk for acquiring HIV-associated opportunistic infections. By achieving goals 1 through 3, goal 4 naturally follows, and this is the ultimate goal of the pharmacotherapy of HIV infection. With modern-day ART, patients infected with HIV are dying more frequently from non–HIV-related conditions common in the general population (ie, cardiovascular disease, hepatic disease, non–HIV-associated malignancies).[97] Although this represents a significant achievement in care, it also provides increased complexity in caring for those who are both at risk for HIV-related illness and also receiving treatment for comorbid conditions. This increases the potential for drug–drug and drug–disease interactions.

The selection of a patient-specific regimen can be a complex decision. Many potential combinations can be used, but a number of general principles should be followed.[3,5]

GOAL 5: PREVENT HUMAN IMMUNODEFICIENCY VIRUS TRANSMISSION

Maintaining a plasma HIV RNA of <200 copies/mL—related to goal 1 above—prevents the sexual transmission of HIV to partners. This is represented by "Undetectable = Untransmittable" or "U=U" and the cornerstone of treatment as prevention (TasP). This has been seen in the PARTNER and PARTNER-2 studies, in which there were zero transmissions in serodiscordant partners.[98,99] In order for U=U to be achieved, high levels of ART adherence must be maintained as transmission may be possible during stretches of less than optimal adherence and/or treatment interruption. This was seen in the HPTN 052 study, which noted in its 2016 analysis that no phylogenetically linked sexual transmission occurred over 5.5 years among couples with a partner on ART and maintaining viral loads <400 copies/mL.[100] In addition, a recent systematic review of 12 clinical studies exploring the association between risk of transmission and undetectable viral load found no transmissions across 10,511 person-years of follow-up when viral load of an infected partner was <200 copies/mL across consecutive measurements regardless of condom use.[14] It must be noted that while adherence to ART prevents transmission of HIV, sexually transmitted infections (STIs) must be routinely screened.

GOAL 6: REDUCE THE LATENT RESERVOIR

It is important for both clinicians and patients to understand that ART will not cure HIV. One barrier to a cure is the establishment of the latent reservoir, a term indicating the persistence of replication-competent virus. The establishment of the latent reservoir occurs within days of initial infection.[101] Because of the time lag between infection and diagnosis, the latent reservoir may already be established. As a result, early initiation of ART will help reduce the size of the latent reservoir as it prevents further cells from being infected with HIV. In the context of future HIV cure strategies that may rely on immunomodulation agents and/or therapies to bring out virus, early initiation of and consistent adherence to ART may be complementary in ultimately eradicating HIV.

General Rules of Therapy

Initiation of therapy should occur soon after diagnosis in most patients.[3,5] Many of the current regimens reduce viral replication to less than detectable levels and result in durable treatment responses. Reasons for the current improved response rates include the simplification of the regimens (eg, fewer pills per day, less frequent dosing per day, use of fixed-dose combination products), improvement in overall potency of the regimens, and minimization of short-term side effects. Consequently, if the correct patient-specific ART regimen is selected as initial therapy, the patient should be able to adhere to therapy and gain both virologic and clinical benefits from the regimen.

Case 76-1, Question 5: On questioning, E.J. admits to having an occasional drink with dinner, but he is not currently using any illicit drugs and has not in 3 years. E.J. has no known drug allergies and is currently taking only omeprazole to help with stomach acid. He is employed as a

construction worker and is extremely busy during the day, so he prefers to take medications only one time daily. His complete blood count, electrolyte, and liver and renal panel all return within normal limits. His baseline genotype does not indicate any transmitted drug resistance, and he is HLA-B*5701-negative. E.J. has no particular preference for a specific regimen and appears highly motivated to take control of his disease. What factors should be considered when selecting an appropriate antiretroviral regimen?

Select the type of antiretroviral regimen. ART regimens typically consist of a combination of two to three agents from at least two classes. In general, INSTI-based ART regimens are preferred (**Table 76-4**). Patient-specific factors, such as comorbid disease states, concomitant medications, and pill burden should be considered.

Table 76-4
Recommended Antiretroviral Agents for Initial Treatment of Established Human Immunodeficiency Virus Infection

	Preferred[a]	Alternatives
PIs (one or two PIs + two NRTIs)	Darunavir/ritonavir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide	Darunavir/ritonavir + abacavir/lamivudine[b]
		Darunavir/cobicistat[c] + abacavir/lamivudine[b] or emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
		Atazanavir/ritonavir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
		Atazanavir/cobicistat[c] + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide
Integrase inhibitors	Raltegravir twice daily + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide	
	Elvitegravir/cobicistat/emtricitabine/tenofovir disoproxil fumarate[c] or elvitegravir/cobicistat/emtricitabine/tenofovir alafenamide	
	Dolutegravir + emtricitabine/tenofovir disoproxil fumarate or emtricitabine/tenofovir alafenamide	
	Dolutegravir/abacavir/lamivudine[b]	
NNRTIs (one NNRTI + two		Efavirenz/emtricitabine/tenofovir disoproxil fumarate

NRTIs)		Rilpivirine/emtricitabine/tenofovir disoproxil fumarate[d] or rilpivirine/emtricitabine/tenofovir alafenamide
Not recommended: Should not be offered	All monotherapies, dual-nucleoside regimens, triple-NRTI regimens	

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; NRTI, nucleos(t)ide analog reverse transcriptase inhibitor; NNRTI, non-nucleos(t)ide analog reverse transcriptase inhibitor; PI, protease inhibitor.

[a]This table provides a guide to the use of available treatment regimens for individuals with no prior or limited experience on HIV therapy. In accordance with the established goals of HIV therapy, priority is given to regimens in which clinical trial data suggest the following: sustained suppression of HIV plasma RNA (particularly in patients with high baseline viral load), sustained increase in $CD4^+$ T-cell count (in most cases >48 weeks), and favorable clinical outcome (ie, delayed progression to AIDS and death). Additional consideration is given to the regimen's pill burden, dosing frequency, food requirements, convenience, toxicity, and drug interaction profile compared with other regimens. It is important to note that all antiretroviral agents have potentially serious toxic and adverse events associated with their use.

[b]Only for patients who are HLA-B*5701 negative.

[c]Only for patients with pretreatment estimated CrCl >70 mL/minute.

[d]Only for patients with pretreatment HIV RNA >100,000 copies/mL and CD4 count >200 cells/μL.

Avoid regimens that are not virologically additive or synergistic. 3TC and FTC should not be used together because they have similar resistance profiles, and concomitant use will not confer any additional virologic benefit.

If PI-based ART is desired, regimens combined with a pharmacoenhancer (eg, RTV and COBI) are preferred. RTV, a potent inhibitor of cytochrome P-450 metabolism and P-glycoprotein (PGP) activity, interacts significantly with a number of agents, including other PIs. This inhibition can be exploited to decrease the metabolism or increase the absorption of the other PIs. In some cases, such as in the use of LPV and DRV, the use of a coadministered pharmacoenhancer is required for virologically relevant concentrations. The result is a regimen with more potent viral suppression. In addition, boosting concentrations with a pharmacoenhancer allows for less frequent dosing, often lowers the total daily pill burden, and removes the need for drug/food restrictions. The pharmacoenhancer, COBI, can also be combined with ATV or DRV (as well as the INSTI, EVG) to provide a similar boosting effect as RTV without providing any antiviral effect. Because RTV and COBI are potent inhibitors of CYP3A4, they interact with a number of medications. Concomitant medications may require dosage adjustments, depending on the severity of the interaction.[3,5]

CASE 76-1, QUESTION 6: What initial ART regimen should E.J. receive?

When selecting a patient-specific regimen, the following steps should be followed.

STEP 1: DETERMINE WHICH ANTIRETROVIRAL CLASS WILL BE USED

A careful review of the advantages and disadvantages of each regimen should occur (**Table 76-5**). For example, PIs may be less favored with a current medical condition consisting of coronary artery disease, hyperlipidemia, or diabetes mellitus because of their potential metabolic side effects.[3,77]

Table 76-5
Advantages and Disadvantages of Antiretroviral Components for Initial Antiretroviral Therapy

ARV[a] Class	Possible Advantages	Possible Disadvantages
Dual NRTI	▪ Established backbone of combination antiretroviral therapy ▪ Less fat maldistribution and dyslipidemia than PI-based regimens	▪ Rare but serious cases of lactic acidosis with hepatic steatosis reported (d4T > ddI = ZDV > TDF or TAF = ABC = 3TC = FTC) ▪ Low genetic barrier to resistance (single mutation confers resistance)
NNRTI	▪ Long half-lives ▪ Single tablet regimens available with EFV and RPV	▪ Low genetic barrier to resistance ▪ Cross-resistance among first-generation NNRTIs ▪ Skin rash ▪ Potential for cytochrome P-450 drug interactions ▪ Transmitted resistance to NNRTIs more common than with PIs and INSTIs
PI	▪ Higher genetic barrier to resistance ▪ PI resistance uncommon with failure (boosted PIs) ▪ More forgiving to intermittent adherence	▪ Metabolic complications (fat maldistribution, dyslipidemia, insulin resistance) ▪ Cytochrome P-450 substrates, inhibitors, and inducers (potential for drug interactions)
INSTI	▪ Well-tolerated ▪ Single tablet regimens available with EVG and DTG ▪ Fewer drug–drug interactions with RAL and DTG than PI- or NNRTI-based regimens ▪ Achieve rapid viral load suppression	▪ Less long-term experience than with boosted PI-based regimens ▪ Lower genetic barrier to resistance than boosted PI-based regimens

ABC, abacavir; ARV, antiretroviral; DHHS, Department of Health and Human Services; DTG, dolutegravir; EVG, elvitegravir; FTC, emtricitabine; INSTI, integrase strand transfer inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitors; NRTI, nucleoside reverse transcriptase inhibitor; PI, protease inhibitor; RAL, raltegravir; TAF, tenofovir alafenamide; TDF, tenofovir disoproxil fumarate; 3TC, lamivudine.

[a]Adapted from DHHS treatment guidelines July 2016. See full guidelines for discussion of the advantages and disadvantages of each individual ARV agent.

After discussions with E.J., it appears that he is highly motivated to take control of his disease and is willing to initiate therapy. Subsequently, the use of a combination

ART regimen with an INSTI-based regimen is appropriate. Potential initial treatment options are listed in Table 76-4.

In the most recent updates to the guidelines, an additional option for first-line regimens is a two-drug regimen. To date, the only recommended combination is DTG/3TC. The rationale of this inclusion was based on the 96-week data from the GEMINI-1 and GEMINI-2 trials.[102] These analyses showed that the rates of virologic control in treatment-naive patients were similar to those of a conventional three-drug regimen consisting of DTG plus FTC/TDF. Of note, this dual regimen is not recommended for individuals with HIV RNA >500,000 copies/mL, hepatitis B virus (HBV) coinfection, or in whom ART is to be started before the results of HIV genotypic resistance testing for reverse transcriptase or HBV testing are available.

STEP 2: OPTIMIZE AGENTS IN THE REGIMEN

The next step requires the selection of agents for the ART regimen. In many situations, absolute contraindications and significant drug–drug interactions limit the agents available for use in the regimen. The nucleoside or nucleotide reverse transcriptase inhibitors, including 3TC, TDF or TAF, FTC, and ABC, are all potential options for E.J. With respect to drug interactions, an INSTI can be administered safely with omeprazole.

STEP 3: QUALITY-OF-LIFE CONSIDERATIONS

When selecting an ART regimen, assessment of quality-of-life issues, potential adverse drug events, and patient preference should receive as much consideration as drug–drug interactions and absolute contraindications. In some situations, these issues could mean the difference between a regimen that is effective and one that is not. Considering E.J.'s lifestyle and work requirements, it is best to select a regimen that will minimally interfere with his daily activities. The selection of a regimen with once-daily or twice-daily dosing is appropriate (see Table 76-2), although once-daily dosing might be preferred. Potential regimens include INSTI-based regimens such as BIC/FTC/TAF, RAL twice daily with FTC/TDF or FTC/TAF once daily, DTG plus FTC/TDF or FTC/TAF all once daily, DTG/ABC/3TC as a combination tablet once daily, or DTG/3TC pending the HBV serology and HIV-1 resistance testing results.

Case 76-1, Question 7: E.J. is starting BIC/FTC/TAF. How should therapy be monitored? Are any additional laboratory tests necessary? What adherence support should be provided?

Short-Term Assessments

Three important criteria determine whether an ART regimen is effective: clinical assessment, surrogate marker responses, and regimen tolerability, including a patient's ability to adhere to the regimen.[3,5] In patients who are clinically symptomatic (eg, constitutional symptoms such as fatigue, night sweats, and weight loss; new opportunistic infections), the initiation of an appropriate antiretroviral regimen often

results in resolution of symptoms, increased strength and energy, and improvement in overall well-being. In some patients, however, the effect may not be as prominent. A careful assessment of clinical symptoms should therefore be regularly performed at all follow-up appointments.

In all patients, repeat viral load and T-cell measurements are necessary. This early value allows clinicians to assess the magnitude of response and ensures declining viral load measurements. ART with an effective regimen will generally result achieve viral suppression 8 to 24 weeks after initiation. Therapy with an effective regimen will result in at least a threefold (0.5 log) and tenfold decrease (1.0 log) in viral load counts by weeks 4 and 8, respectively.[3,5] The viral load should continue to decline during the next 12 to 16 weeks, and, in most patients, it will become undetectable.[3,5] Long-term response to therapy correlates with the magnitude of viral suppression on initiation of a regimen. The greater the suppression, the greater the durability of response to that regimen.[103] The speed and magnitude of suppression, however, can be affected by a number of factors, including clinical status of the patient (eg, more advanced disease–low T-cell counts, high viral load value), adherence to therapy, and overall potency of the regimen.[3,5]

In response to declining viral replication, T-cell destruction slows, and eventually cellular repopulation occurs. The magnitude of this T-cell increase can vary significantly, with some patients experiencing large increases (≥500 cells/μL) and others experiencing little or no change. Given that T-cell changes do not occur rapidly, once therapy is initiated, repeat T-cell counts should be obtained at 3-to 4-month intervals.[3,5]

A seemingly worsening of symptoms may also occur after the initiation of potent antiretroviral therapies because of immune reconstitution.[104–106] In patients with advanced HIV disease (ie, CD4 <100 cells/μL), significant immune dysfunction results in an inability to mount an appropriate response to subclinical infections. As a result, these infections replicate unimpeded and often undetected by the host (also known as quiescent disease). During the first 12 weeks of therapy, an increased immune response results from redistribution of memory cells,[107–109] and inflammation occurs at the site of infection. The immune reconstitution inflammatory syndrome can present in any organ system where quiescent disease exists (eg, CNS, eyes, lymph nodes). Most cases occur within 1 to 4 weeks after the initiation of potent antiretroviral therapies.[3]

A patient's tolerability of the regimen, which includes involvement in the decision of what therapy to initiate, ease of administration, and avoidance of intolerable side effects, is vital to a patient's willingness and ability to adhere to an antiretroviral regimen. If the patient is not adherent, they are at risk for clinical failure and the development of resistance. Adherence should be evaluated at every clinic visit, and the type and reason for identified nonadherence should be assessed. If adherence is not a present concern, then positive reinforcement and encouragement are recommended.[3]

Case 76-1, Question 8: After initiation of therapy, E.J.'s viral load values are 7000 copies/mL at 4 weeks and <50 copies/mL (undetectable) at 12 weeks. His T-cell counts have increased from 225 to 475 cells/μL. In addition, E.J. states that his night sweats and fevers have disappeared, he "feels great," and that he has had no drug-related problems. Is the therapy effective? How should therapy be monitored?

E.J.'s response to BIC/FTC/TAF does indicate efficacy. Clinically, his symptoms have subsided, and his overall health is much improved. His viral load measurements have responded appropriately and are now less than the level of assay detection. T-cell counts have increased by 250 cells/μL. Finally, E.J. has experienced no drug-related adverse events. Given the response to date, no changes are required, and the current regimen should be continued.

Long-Term Assessments

Once the prescribed regimen has been stabilized, the long-term goals are to maintain maximal viral suppression, sustain clinical and immunologic improvements, and maintain drug safety and tolerability. Periodic assessments should be made of viral load and T-cell counts (every 3–6 months), and potentially even annually after demonstrating a consistent and reliable history of undetectable viral load assessments[3,5] These surrogate marker data allow clinicians to monitor trends in viral activity and immunologic status and assist them in identifying early regimen failure. Clinical assessment of the patient questioning of tolerability and adherence to the prescribed regimen should occur at the 3- to 6-month follow-up visits. Lastly, routine laboratory safety monitoring should occur as part of the clinical care and more frequently as warranted.

Treatment Failure

Case 76-1, Question 9: E.J. has remained on BIC/FTC/TAF for more than a year. To date, his T-cell counts have remained stable at 550 cells/μL, and his viral load measurements have remained less than the limit of assay detection. He presents with new complaints of fevers and malaise. E.J. reports that he has been concerns with therapy and has not started any new medications. Repeat laboratory tests now show E.J.'s viral load is 3000 copies/mL and his T-cell count is 375 cells/μL (both repeated and validated). Should E.J.'s regimen be changed?

Assessment of regimen failure should be based on (a) clinical symptoms, (b) surrogate marker data, and (c) regimen tolerability and adherence.[3–5]

In some patients, the first sign of failure is a change in signs and symptoms. These changes can be subtle (eg, increase in constitutional symptoms, new onset of oral thrush) or more severe (eg, new opportunistic infections) and suggest a failing regimen and need to change therapy.

Assessment of efficacy should also involve evaluation of surrogate marker data (eg, T cells and viral load). In many situations, changes to these markers occur

before any noticeable clinical signs and symptoms. Therefore, careful evaluation of surrogate marker data may allow for intervention before any significant immune destruction occurs. Virologic failure, defined as new or continued viral replication despite appropriate ART, suggests a failing regimen. For example, patients with repeated detection of virus in plasma after initial suppression to undetectable levels should be evaluated as potential treatment failures. In patients who do not achieve viral suppression to less than detectable levels, a significant increase in viral replication should also be viewed as a treatment failure.[3],[4]

When assessing viral load, it is important to recognize that these values can increase from vaccinations or other concurrent infections (see Case 76-1, Question 2). Therefore, a thorough medical history should be taken to rule out other causes of increasing viral load. In addition, laboratory values should be interpreted as trends over time and not necessarily as individual measurements. A repeat viral load should be performed and evaluated within 4 weeks of the initial viral load increase. In some cases, transient viral "blips" occur (increases in viral load measurements just above the level of assay detection (eg, 50–1000 copies/mL), which become undetectable at the next visit.[109],[110] The clinical significance of viral blips is unknown, and, although they may not directly reflect treatment failure, they may represent near-future viral breakthrough because of either patient nonadherence or insufficient antiretroviral potency.[111],[112] Careful follow-up of these patients is required, because changes to the current ART regimen may be necessary.

In response to increasing viral replication, T-cell destruction occurs. Persistently declining T-cell counts, with or without increasing viral load measurements, represent treatment failure and suggest a change in therapy is warranted.

Other potential causes for failure include nonadherence and drug–drug interactions. In the event of nonadherence, discussions regarding tolerability, number of doses missed, duration of nonadherence, and lifestyle changes should take place. The decision to reinitiate a prescribed regimen should take into account the future likelihood of adherence and the potential development of resistant strains. In those patients with a history of long-standing nonadherence, the success of reinitiating the prescribed regimen may be limited. Stopping all ART at once poses less risk for the development of resistance than intermittent adherence to some or all of a regimen. The precise effect of the duration and extent of nonadherence on the development of resistance cannot be fully anticipated and is dependent on the barrier to resistance of the patient's ART. For the virus to mutate, sufficient drug pressure must be placed on the virus.

Significant drug interactions could also contribute to reduction in oral bioavailability or increased metabolism of the HIV medications leading to low serum concentrations, resulting in failure.[3] In addition, many medications require certain food requirements to allow maximal drug absorption. A careful review of all new medications and their potential for clinically significant drug interactions should be evaluated at all visits (Table 76-5).

Currently, E.J. has a number of signs and symptoms that suggest a failing regimen. E.J. is experiencing new symptoms of fevers and malaise not attributable to any

other cause. E.J.'s viral load value has become detectable at 3000 copies/mL without evidence of concurrent infections or vaccinations in the past 4 weeks. E.J.'s T-cell counts have declined from 550 to 375 cells/μL. Finally, it appears that E.J. has been adhering to his therapy and has not started any new medications that could affect the efficacy of his current regimen. Therefore, a change in therapy is necessary.

CASE 76-1, QUESTION 10: What potential antiretroviral regimen(s) can be considered for E.J.?

In addition to the general rules of therapy described in Case 76-1, Question 5, other issues should be considered when selecting an alternative regimen for a patient failing therapy.[3,4]

GENERAL RULES FOR CHANGING THERAPIES

1. If possible, the new regimen should contain at least two, preferably three, fully active agents. The potential for cross-resistance between ART should be considered when choosing new regimens, and therefore resistance testing should provide useful information (see Case 76-2, Question 2).
2. Given that antiretroviral drug resistance is more likely to occur with increased and prolonged viral replication in the presence of ART, changes to therapy should occur close to the time of treatment failure. Prolonged treatment with a failing regimen is likely to result in the accumulation of resistance mutations (particularly with PIs), which may limit future treatment options.
3. Resistance testing is recommended to guide the selection of future drug regimens. Optimally, testing via genotype, phenotype, or virtual phenotype should occur while the patient is taking the failing regimen or within 4 weeks of discontinuation to increase the likelihood of detecting resistant isolates. These tests cannot reliably detect mutations at viral concentrations <1000 copies/mL and may have limited usefulness in patients with persistent low-level viremia.
4. To prevent the development of resistance, one new drug should never be added to a failing regimen. An exception to this rule is if the initial response to a first regimen has been inadequate (eg, undetectable viral load at 16–20 weeks). In this situation, some clinicians may intensify therapy with an additional agent provided that the viral load measurements were trending downward since initiation of therapy.
5. If possible, a regimen that has failed in the past should not be reinitiated, because an isolate resistant to the failed regimen could continue to reside within various compartments of the body. If a regimen to which the patient had previously failed were restarted, unimpeded viral replication of the resistant strain would occur, repopulate the host, and eventually result in treatment failure. In some situations (eg, patients with advanced disease, limited treatment options, and prior exposure to most ART), it may be necessary to reinitiate agents or regimens in combination with additional new agents with the goal of suppressing viral replication.

6. When treatment failure is a direct result of drug toxicity (rather than poor drug efficacy), the offending agent should be replaced with an alternative drug from a similar class, provided that the potential for cross-resistance is minimal.
7. If an agent in a given regimen must be stopped, it is recommended that all agents in the regimen be stopped and restarted simultaneously to prevent the development of resistance.

It should be recognized that many alternative regimens are based on theoretical benefits or limited data. In addition, many potential options could be limited in some patients based on prior antiretroviral use, toxicity, or past intolerances. Therefore, the clinician should carefully discuss these issues with the patient before changing therapy.

Because E.J. is failing to respond to his current regimen, a new ART regimen must be chosen. In addition to selecting susceptible agents from resistance testing, the new regimen should take into consideration quality-of-life issues. In E.J.'s situation, it is reasonable to switch to a PI-based ART regimen, with two or more nucleoside agents as dictated by the viral resistance profile.

Considerations in Antiretroviral-Experienced Patients

CASE 76-2

Question 1: H.G. is a 56-year-old male infected with HIV with an extensive history of ART with a variety of ART. He took AZT monotherapy in the late 1980s and early 1990s. When 3TC became available, he took the combination of AZT and 3TC until he failed therapy about 25 years ago. At that time, he began experiencing AZT-induced myopathies. Since that time, H.G. has been "on and off" various regimens without sustained clinical benefit. He is currently taking FTC/TDF and ATV/r with a CD4 count and viral load measurement of 55 cells/μL and 48,000 copies/mL, respectively. These laboratory values have been stable for the last 9 months.

How do patients with extensive antiretroviral histories differ from antiretroviral-naive patients? Are there any special considerations when selecting therapeutic regimens for patients such as H.G.?

Patients who have been infected for 20 or more years may have been treated with many different regimens, both experimental and FDA approved. As a result, many potential regimens have already been exhausted; thus, there are fewer viable choices left. Agents with higher barriers to resistance that do not have cross-resistance with older agents and agents with novel mechanisms of action are useful in these patients. Although, DRV was specifically marketed for highly treatment-experienced patients because of its high genetic barrier to resistance and limited cross-resistance with other PIs.[3,4] The second-generation NNRTIs, DOR, ETR, and RPV, have minimal cross-resistance with the first-generation NNRTIs, EFV and NVP.[3,4] MVC, the first CCR5 receptor antagonist approved by the FDA, is also an option for treatment-experienced patients infected with HIV-1 utilizing this co-receptor and failing current treatment. MVC is not recommended for use in patients with dual-tropic viral populations (ie, able to use CXCR-4 or CCR5 as co-receptors) or CXCR-

4–trophic virus, and, thus, patients with extensive treatment histories should undergo tropism testing before MVC is initiated. Although INSTIs had historically been used in patients with extensive reverse transcriptase or PIs mutations, INSTI-based regimens have been first-line agents for years and therefore treatment-experienced patients may have started on INSTIs. Some highly treatment-experienced individuals will have extensive resistance patterns that limit their therapeutic options. In such patients, full suppression of viral load and immune reconstitution may not be possible.[3],[4] Two newer agents have been approved for the management of patients with virologic failure: ibalizumab and fostemsavir. Patients with ongoing detectable viremia who have exhausted first- and second-line treatment options could be candidates for ibalizumab.[3] Fostemsavir has been studied in clinical trials in treatment-experienced subjects with multiclass resistance with viral loads of at least 400 copies/mL.[51],[113] Recommendations for fostemsavir, however, have not been formalized in the guidelines.

Patients who have experienced several antiretroviral regimens present other unique challenges for clinicians and require consideration of the following factors.

1. *Regimen tolerability*: Patients with advanced HIV disease display decreased tolerability to many medications, including ART. Although this is not fully understood, it is probably a result of HIV-induced immune alterations and cytokine dysregulations. Subsequently, clinicians evaluating patients with advanced disease should be alert for possible drug-induced adverse events.
2. *Drug interactions*: Many patients with advanced disease take numerous medications for primary or secondary prophylaxis of various opportunistic infections, as well as other medications for comorbid disease states. Subsequently, the risk for a drug–drug interaction is increased. The addition of any new medication, either prescription or over-the-counter, should be carefully evaluated for potential interactions with the patient's current ART regimen (see **Table 76-6**). In addition, any change to the current ART regimen should also be checked against the patient's current medication list.
3. *Altered bioavailability*: Patients with advanced HIV infection may have unreliable absorption of many medications because of severe diarrhea, anorexia, weight loss, wasting, and gastric achlorhydria. As a result, the bioavailability of some agents may be affected (Table 76-2). Any changes in dietary habits or bowel function should be carefully assessed in light of the potential impact on the ART regimen.
4. *Antiretroviral drug histories and resistance testing*: The most useful information to guide the choice of alternative ART regimens is a detailed drug history, in conjunction with appropriate resistance testing. Among patients with extensive prior antiretroviral use, it is critical to identify previously failed regimens and determine the precise cause of the failures. In an experienced patient who has taken many different regimens over a lifetime, the number of remaining viable agents and regimens may be limited. Therefore, it is important to determine whether prior regimens truly failed for virologic reasons or some other cause (eg, regimen intolerability, nonadherence, or an inadequate trial period). In addition, detailed

knowledge of regimen intolerabilities and which agent(s) caused the adverse event will help in the selection of a new, appropriate ART regimen. In some situations, the offending agent may be reinitiated if the adverse event was minimal or can be appropriately managed.

Table 76-6
Metabolism and Drug–Drug Interaction Potential of Antiretroviral Classes

Class	General Metabolism and Drug–Drug Interaction Considerations	Exceptions
NRTIs	Renally eliminated, few drug–drug interactions	ABC is metabolized by alcohol dehydrogenase and competes with alcohol for metabolism.
NNRTIs	CYP3A4 substrates CYP3A4 inducers	RPV is a CYP3A4 substrate only. ETR is also a CYP2C9, CYP2C19 substrate/inhibitor.
PIs	CYP3A4 and PGP substrates CYP3A4 inhibitors	RTV is also a CYP2D6 substrate/inhibitor. ATV also inhibits UGT1A1. TPV is also a CYP2D6 inhibitor and PGP inducer.
INSTI	UGT1A1	EVG is a CYP3A4 substrate, given with COBI a potent CYP3A4 inhibitor. DTG is also a UGT1A3 and PGP substrate.
CCR5	CYP3A4 substrate	

ABC, abacavir; CCR5, chemokine co-receptor 5; COBI, cobicistat; DTG, dolutegravir; EVG, elvitegravir; ETR, etravirine; INSTI, integrase strand transfer inhibitor; NRTI, nucleos(t)ide reverse transcriptase inhibitor; NNRTI, non-nucleoside reverse transcriptase inhibitor; PGP, P-glycoprotein; PI, protease inhibitor; RPV, rilpivirine; RTV, ritonavir; TPV, tipranavir.

RESISTANCE, VIRAL GENOTYPING, PHENOTYPING, AND VIRAL FITNESS

CASE 76-2, QUESTION 2: Will viral genotyping and phenotyping assist in selecting an appropriate therapeutic regimen for H.G.? What are these tests? What are their limitations and when should they be used? What is viral fitness, and does it have a role in clinical decision-making?

Viral genotyping and phenotyping reveal resistance patterns to ART. Genotyping evaluates mutations in the virus's genetic material, whereas phenotyping assesses the ability of the virus to grow in the presence of increasing concentrations of ART. The three potential causes for the development of resistance are as follows.

1. Initial infection with a resistant isolate[114–116]
2. Natural selection of a resistant isolate as a consequence of inefficient, error-susceptible viral replication[35]
3. Generation of resistant isolates via selective pressures from ART that does not fully suppress viral replication[3,4]

Mutations are generated when naturally occurring amino acids in the HIV genome are replaced with alternative amino acids. For example, resistance to 3TC occurs when the amino acid methionine (M) is replaced by valine (V) at the 184th amino acid in the protein chain.[117],[118] This mutation is subsequently referred to as an M184V mutation. These amino acid substitutions change the proteins that are produced and may alter the shape, size, or charge of the viral enzyme's substrate or primer.[118] Subsequently, antiretroviral drug binding to the active site is decreased, affinity for natural substrates is increased, or there is an increased removal of the antiretroviral agent from the enzyme by the virus (known as pyrophosphorylation).[116] Whether a mutation results in a clinically resistant, less viable, or indifferent isolate depends on which amino acid(s) is replaced. In addition, certain mutations or combination of mutations have been shown to produce viral isolates that display increased sensitivity to various ART (known as hypersusceptibility). Alterations to certain key amino acids can also result in cross-resistance between various ART.[4],[117]

Key enzymes have been extensively studied regarding their potential for development of resistance: reverse transcriptase (RT), protease, and, more recently, integrase. Replication by the RT enzyme is highly susceptible to errors. Given that the HIV genome is ~10,000 nucleotides in length and that mutations via the RT enzyme occur approximately once in every 10,000 nucleotides copied, it has been estimated that a mutation occurs with every viral replication cycle. With up to 10 billion particles of virus being produced per day, the potential exists for 1000 to 10,000 mutations occurring at each site in the HIV genome every day.[35] Key mutations to the ART are updated periodically by expert panels of clinicians.[4]

Over time, countless viral subpopulations known as "quasi-species" develop. In any given host, at any given time, many different quasi-species can exist. In addition, within any compartment of the body (eg, CNS, testes, lymph nodes), many different quasi-species can also exist. Because these mutant strains represent only a small number of isolates in the total viral population, they must have some replicative disadvantage when compared with the "wild-type" virus.[117] Under selective pressures from ART, however, these mutant isolates can replicate. For example, if wild-type viral replication is inhibited by an ART regimen, and if any one viral strain of the quasi-species is more fit for growth in the presence of that regimen, then the viral mutant will have a competitive advantage.[117] It should be recognized that for resistance to develop, viral replication must occur. When viral replication is completely inhibited, the development of resistant isolates is unlikely.

Genotypic analysis involves sequencing the viral genetic material via PCR amplification. Mutations are identified by analysis of key sequences of the RT or protease enzymes. These tests can be rapidly processed; however, they detect mutations present only in more than 25% of all HIV isolates in the body and can only reliably detect resistance patterns in samples with HIV RNA >1000 copies/mL. Because pressure from ART selects resistant isolates, these tests may not provide information regarding rare, yet potentially clinically significant, isolates.[3],[4]

Phenotypic analysis involves growing virus in the presence of various concentrations of drug and then determining viral susceptibilities (eg, half-maximal

inhibitory concentration [IC_{50}]). Phenotyping is limited because it evaluates only one viral isolate at a time and could fail to identify other clinically relevant isolates.[3]

In the case of ART-experienced patients with suspected drug resistance and limited or incomplete antiretroviral and resistance history, obtaining medical records —if possible—alongside resistance testing is helpful to identify mutations.[3] Clinicians should keep in mind that it is possible that specific mutations may not be detected with the absence of drug pressure (eg, resistance testing of replicating virus from genotyping may not reflect "older," mutated virus). Similar to other resistance mechanisms, the goal here is resuppression.

One other measure available to clinicians is "viral fitness" or "replication capacity." The genetic changes that occur in a virus to become resistant to ART often impair the virus' ability to replicate.[119],[120] This measure is called "fitness" and is quantified as replication capacity during phenotypic evaluation. During amplification of the virus before the phenotype is measured, the replication capacity of the virus is evaluated and compared to a reference wild-type, drug-sensitive virus. A virus with normal fitness has a replication capacity between 70% and 120% of the reference viral strain; isolates with values <70% are considered to be less fit than wild-type virus. In general, the more mutations that occur to the virus, the more compromised the virus becomes, and the lower the fitness (although, in some situations, the interplay between mutations can result in a viral isolate that is relatively fit). Recent data have shown that, despite persistent viral replication, unfit viruses may not cause the same degree of immune destruction as fit viruses.[118] This finding is important for patients with limited treatment options because it may allow for continuation of an ART regimen that is not completely suppressive, but that produces an unfit virus, with less T-cell depletion.

As with all clinical decisions made for PLWH, careful assessment of the results in combination with the treatment history are essential for proper clinical decision-making. Consultation with an expert in antiretroviral drug resistance patterns is highly recommended. Furthermore, specific actions for ART options for patients with virologic failure can be found in Table 11 (https://clinicalinfo.hiv.gov/sites/default/files/guidelines/documents/AA_Tables.pdf) of the 2019 DHHS HIV treatment guidelines.

Given H.G.'s extensive antiretroviral drug history and his current failure, a genotype or phenotype will likely provide some insights into potential therapeutic options.

SPECIAL CIRCUMSTANCES

Poor CD4 Cell Recovery

Case 76-2, Question 3: H.G. was started on a regimen of TAF, FTC, DTG, and DRV boosted with RTV. During the following 6 months, H.G.'s T-cell counts increased to 325 cells/μL and his viral load value declined to 5000 copies/mL. At the last two clinic visits, H.G.'s viral load and CD4 counts were 2000 copies/mL/275 cells/μL and <20 copies/mL/225 cells/μL, respectively. H.G. reports no new clinical complaints or adverse drug events. In addition, H.G. states that he has been concerns with therapy. Are changes to therapy necessary?

In most cases, declines in viral load result in increases in CD4 cell counts; however, in some cases, CD4 cells fail to recover with viral load suppression.[5] In this situation, it may be wise to continue current treatment and monitor the patient closely. Adding an additional drug to intensify the regimen or changing to a different ART regimen does not consistently increase the CD4 cell count and is not recommended.[3]

Therapeutic Drug Monitoring

PK evaluations of various ART have shown interpatient variability in drug exposures among cohorts of patients taking the same dose of drug under the same conditions.[3,120–123] Many factors contribute to interpatient variability in drug exposure, such as pharmacogenetics, environment, different physiologic conditions, regimen adherence, and drug interactions. For most ART, a drug exposure–response relationship exists (eg, the higher the exposure, the faster and more prolonged the viral suppression). In addition, most ART also have well-defined exposure–toxicity relationships.

Therapeutic drug monitoring (TDM) is currently recommended for limited clinical situations, including the use of concomitant medications with known drug interactions, clinical scenarios of impaired drug absorption, and certain clinical scenarios of pregnancy.[3,122] For patients with these scenarios of altered absorption, distribution, metabolism, or clearance, drug concentrations may help identify low or high exposure that can be corrected with a dosage adjustment. For proper interpretation of the concentrations, patients should provide a dosing history from the last several days, a list of concomitantly administered drugs to screen for interactions, and the exact time the last dose was taken. The exact time the TDM sample was collected should also be recorded. Clinicians should consult a pharmacology expert to determine a maximally informative TDM sampling strategy and select a laboratory that routinely measures ART and participates in both internal and external quality control programs to minimize laboratory variability and error in measuring these concentrations. A list of such laboratories can be obtained from the Clinical Pharmacology Quality Assurance and Quality Control Program (https://www.fstrf.org/apps/cfmx/apps/cpqa/cpqaDocs/public/index.html).

Drug Interactions

CASE 76-3

Question 1: J.F. is a 37-year-old male infected with HIV who has been taking EVG/c, TDF, and FTC for the past 4 years. His most recent lipid panel showed markedly elevated triglycerides, LDL, and total cholesterol.

What needs to be considered when starting a lipid-lowering medication for J.F.?

Drug interactions are very common with certain classes of ART, including PIs, PK enhancers, and NNRTIs, but less common with INSTIs and NRTIs. The potential for interactions should be considered when changing HIV-related or nonrelated drug regimens. In this case, COBI will significantly increase the concentrations of HMG-CoA reductase inhibitors that are metabolized by CYP3A4 through inhibition of the CYP3A4 isoenzyme.[3] Increased concentrations of the HMG-CoA reductase inhibitor could put J.F. at risk for myalgias and rhabdomyolysis. If J.F.'s lipids require treatment with an HMG-CoA reductase inhibitor, one that is only partially metabolized by CYP3A4 or metabolized by another pathway should be considered. Simvastatin and lovastatin are contraindicated in combination with the PK enhancer, COBI, but pravastatin, pitavastatin, rosuvastatin, and atorvastatin can be used at reduced doses.[3] The DHHS HIV adult treatment guidelines have extensive tables outlining specific drug interactions and recommendations for concomitant use of medications with the ART.[3] Table 76-6 gives the general metabolism and transport effects of each of the classes of ART and gives an idea of the drug interaction potential of each class.

Pregnancy and Breast-Feeding

CASE 76-4

Question 1: T.D. is a 32-year-old female infected with HIV, whose ART includes the combination tablet DTG/ABC/3TC once daily. Her virus is fully suppressed, and her CD4 cells count is 786 cells/μL. She has had a positive home pregnancy test result, and her last period was 2 months ago.

Is her current antiretroviral regimen appropriate for use during pregnancy and for prevention of mother-to-child transmission?

The current perinatal HIV guidelines[124] recommend that females receiving and tolerating a currently suppressive regimen when they become pregnant continue on that regimen as long as there are no risks to the female or fetus. EFV is the only antiretroviral that is currently pregnancy category D and is not recommended during the first 8 weeks of pregnancy. It has been shown to be teratogenic in animal studies, particularly in the first trimester of pregnancy, and retrospective case reports of neural tube defects in humans have been documented.[125–128] In 2019, a birth-outcomes surveillance study of 119,477 deliveries in hospitals throughout Botswana found a slightly higher rate of neural tube defects among infants born to females taking DTG containing versus non–DTG-containing ART (3 vs 1 per 1000 deliveries, respectively).[129] Importantly there is no folate fortification of food in Botswana as in the United States. It is uncertain how folate fortification might impact these findings

and whether these findings in Botswana translate to other geographical regions like the United States.

Perinatal transmission prevention guidelines recommend ABC/3TC, FTC/TDF, or 3TC with TDF as first-line NRTIs for ART initiation in pregnancy. ATV/r and darunavir/r are the recommended PIs for initiation in pregnancy, and RAL and DTG are the recommended INSTIs for initiation in pregnancy. However, given the possible increased risk of neural tube defects, DTG is considered an alternative INSTI that may be considered in certain clinical situations in females who are trying to conceive. Alternative agents for initiation in pregnancy include AZT/3TC, LPV/r, EFV as long as it is initiated after 8 weeks of pregnancy, and RPV.[124] Many of the pregnancy recommendations are based on those drugs that have the most safety and efficacy data available during pregnancy (both animal and human).[124]

In females who have a viral load persistently >1000 copies/mL, it is recommended that a planned 38-week cesarean section be performed to reduce the risk of mother-to-child transmission. In females with a viral load <1000 copies/mL, there is little evidence to show that cesarean section decreases transmission rates compared to vaginal delivery. In this case, the decision is made at the discretion of the physician in consultation with the mother. Additionally, if the mother's viral load is >1000 copies/mL or unknown at the time of delivery, it is recommended that intravenous AZT be administered to the mother at 2 mg/kg intravenously (IV) for 1 hour at the onset of labor, then given as a continuous infusion of 1 mg/kg/hour during the intrapartum period (during labor and postpartum). Once delivered, newborns that are at low risk for perinatal transmission (ie, those born to females with suppressed viral load near the time of delivery) should receive oral AZT at 4 mg/kg every 12 hours for 4 weeks. Newborns at higher risk for perinatal transmission (ie those born to females who did not receive antepartum ART or those who did not achieve viral suppression or had acute HIV infection at the time of birth) should receive up to 6 weeks of presumptive HIV therapy with oral AZT plus 3TC with either NVP or RAL (see the Perinatal guidelines[124] for age- and weight-based dosing recommendations). It is recommended that the infant undergo diagnostic virologic testing using either HIV DNA PCR or RNA virologic assays at a minimum at ages 14 to 21 days, 1 to 2 months, and 4 to 6 months. Antibody testing should not be considered a definitive exclusion or confirmation of HIV infection in a perinatally exposed infant because maternal HIV antibody crosses the placenta and may be detectable in an HIV-exposed infants for up to 24 months of age.[124]

It is not recommended that females infected with HIV breast-feed their children in resource-rich settings where clean water and formula are reasonably available. However, with clear evidence that virologically suppressed individuals do not transmit HIV,[13] guidelines from these resource-rich settings now indicate that mothers who receive adequate counseling about the risks of HIV transmission via breast-feeding and still choose to breast-feed should be supported in their choice. Recommendations to mitigate risk of transmission through breast-feeding include monitoring maternal plasma viral loads every 1 to 2 months during breast-feeding to ensure virologic suppression; exclusive breast-feeding for 6 months before the

introduction of solids, at least 6 weeks of AZT with or without NVP prophylaxis for the infant; promptly identifying and treating maternal mastitis and infant thrush; and monitoring the infant for HIV infection every 3 months throughout breast-feeding, followed by monitoring at 4 to 6 weeks, 3 months, and 6 months after cessation of breast-feeding.

J.F. presents at 2 to 3 months of pregnancy on a fully suppressive ART regimen that she is tolerating well. Although limited evidence suggests that DTG may confer a slight increase in the risk of neural tube defects, these defects most frequently occur before the neural tube closes at 4 weeks postconception or ~6 weeks post-last menstrual period. After 6 weeks gestation, the additional risk of neural tube defects developing is thought to be much less likely. Thus, J.F. should continue on her current ART regimen, and if she remains undetectable throughout her pregnancy, the decision of whether to have a cesarean or a vaginal delivery will be at the discretion of J.F. and her physician.

Preexposure Prophylaxis

CASE 76-5

Question 1: F.C. is a 22-year-old, healthy female who is HIV-uninfected with multiple male sex partners. She reports infrequent condom use but would like to consider therapeutic options to mitigate her risk of pregnancy and STIs.

What prevention methods can be offered to F.C.?

PrEP is the use of ART in HIV-uninfected individuals to prevent HIV infection. The PrEP Clinical Practice Guidelines recommend PrEP as one prevention option for adults at substantial risk of HIV acquisition through sexual behaviors or injection practices.[130] Substantial risk is defined as any individual not in a monogamous partnership with a recently tested HIV-negative partner who in the last 6 months has engaged in condomless receptive or insertive anal sex, who frequently engages in condomless receptive or insertive vaginal sex, or who was diagnosed with a bacterial STI. Additionally, PrEP may be discussed with HIV-uninfected heterosexual females and males whose partners are HIV-infected as one of several options to protect the uninfected partner during conception and pregnancy. Fixed-dose combination tablets of FTC 200 mg with TDF 300 mg (FTC/TDF) and FTC 200 mg with TAF 25 mg (FTC/TAF) have been FDA approved for use as PrEP.[131],[132] Although FTC/TDF is indicated to reduce the risk of any type of sexually acquired HIV infection, FTC/TAF's indication excludes receptive vaginal sex. This distinction is because the study population of the phase III trial demonstrating FTC/TAF's noninferiority to FTC/TDF excluded cisgender females.[81] Event-driven PrEP (ie, two pills within 24 hours prior to sex and one pill at 24 and 48 hours post sex) may also be considered to protect against sexual acquisition for males who have sex with males.[5] HIV testing should be done immediately before PrEP is prescribed and every 3 months while taking PrEP. If a patient is found to be HIV-infected, PrEP should be immediately converted to an

HIV treatment regimen without waiting for additional laboratory results. PrEP should always be provided in conjunction with behavioral risk reduction support and medication adherence counseling. In addition to regular HIV testing and risk reduction counseling, renal function testing should be performed at baseline, 3 months, and then every 6 months thereafter, and STIs should be screened for at baseline and every 6 months.[130] The continued need for PrEP should be evaluated every 12 months, and patients wishing to discontinue PrEP should be counseled that protection will wane over 7 to 10 days following cessation. Alternative methods to reduce risk for HIV acquisition should be discussed.

Although not yet approved for PrEP, LA-CAB has been studied in two phase III trials. HPTN 083 enrolled HIV-uninfected males who have sex with males and transgender females who have sex with males to assess noninferiority of the investigational treatment (5 weeks of daily oral CAB followed by IM injections every 8 weeks of LA-CAB) versus daily oral TDF/FTC standard of care.[133] The study was terminated early because of LA-CAB demonstrating a 66% reduction in HIV incidence when compared to oral PrEP.[133] Importantly, on average nearly 25% of the participants in the daily oral PrEP arm were taking less than 4 doses per week.[133] Suboptimal adherence is likely linked to the inferior protection and evidences the need for less burdensome dosing modalities in HIV PrEP. Additionally, HPTN 084 had an identical study design as HPTN 083 but enrolled HIV-uninfected cisgender females.[134] The blinded trial was stopped in November 2020 after LA-CAB was shown to be superior to the oral PrEP arm (89% reduction).[134] It was noted that only 62% of the plasma samples had detectable TDF/FTC, and <50% of them were consistent with daily dosing.[134] Given these contrasting results, time will tell how regulatory agencies will adjudicate potential approval of LA-CAB for PrEP in different patient populations.

FTC/TDF one tablet daily can be considered for F.C. to reduce her risk of acquiring HIV through receptive vaginal sex. She will need to have baseline HIV, STI, and renal function testing as well as medication adherence and behavioral risk reduction counseling. She will need to follow up 3 months after FTC/TDF prescribing for monitoring and repeat HIV testing. She should be counseled that PrEP does not protect against the risk of other STIs or pregnancy.

Postexposure Prophylaxis

CASE 76-6

Question 1: L.T. is a 47-year-old female nurse at an HIV clinic. While drawing routine labs on a newly diagnosed PLWH, not yet started on ART, she accidently stuck herself with a contaminated needle.

Are interventions available to prevent L.T. from contracting HIV from the needle stick? What drugs should be utilized, and for how long?

PEP is the use of ART to prevent HIV infection in individuals who have had an exposure to blood or body fluid either known to be infected with HIV or potentially infected with HIV. Occupational exposures require immediate evaluation with a first dose of ART offered within the first 2 hours following exposure.[135],[136] PEP is more effective the earlier it can be initiated, and it should always be started within 72 hours of exposure. Percutaneous exposure poses more of a concern than mucous membrane exposure. A needle stick with a large hollow-bore needle is higher risk than a solid needle, a deep penetrating wound is considered a high-risk exposure compared to a superficial injury, and an exposure to a large volume of infectious fluid is more concerning than exposure to a low volume. Patient-specific factors must also be considered, such as whether the PLWH is on ART therapy and has a suppressed viral load or whether the PLWH currently has a high viral load. Regardless of the type of exposure or risk factors, current guidelines recommend that PEP be offered to all health care workers with an exposure. If the source patient is known to be HIV-infected or the HIV status is not known, PEP should be continued for a total of 4 weeks, or 28 days. If the source patient's status is unknown but is later determined to be HIV-negative, then PEP can be discontinued prior to 28 days.[135],[136]

Three-drug PEP is recommended for all health care workers exposed or possibly exposed to HIV. Recommended regimens include two NRTIs with RAL (400 mg twice daily), RAL-HD (1200 mg once daily), or DTG. Females of childbearing potential should be counseled on the potential risk of DTG, as described in the Pregnancy and Breast-Feeding section. Alternative regimens include two NRTIs with a boosted PI.[136]

In instances where the source patient is a known treatment-experienced patient with HIV, the choice of agents to use for PEP is generally dependent on the patient's ART regimen and resistance profile.[135],[136]

L.T. should start a PEP regimen immediately, preferably FTC/TDF once daily with RAL (once- or twice daily depending on formulation) or DTG (once daily). This entire regimen should be continued for a total of 4 weeks. It would also be a good idea to look at the specific patient from which the exposure occurred. If he had a great deal of known antiretroviral drug resistance, then L.T. may need to be put on different ART according to the patient's resistance profile. HIV antibody testing using ELISA should be performed on L.T. at baseline exposure, 6 weeks, 12 weeks, and 6 months after exposure. She should also have baseline and follow-up labs performed to assess antiretroviral toxicity. At a minimum, these should include a complete blood count, renal and hepatic function tests, and fasting glucose while on the PI. Additional laboratory tests should be performed based on the individual drugs chosen.[135],[136]

Additional guidelines exist for nonoccupational HIV exposures and follow similar risk and stratification treatment paradigms. In those instances where a person seeks care within 72 hours of exposure to blood, genital secretions or other potentially infected body fluids of persons known to be HIV-infected and the exposure represents a substantial risk for HIV transmission then the person is started on PEP in a similar fashion as with an occupation exposure and continued for 4 weeks with similar monitoring and HIV testing.[135]

In 2019, California Senate Bill 159 (CA SB 159) sought to improve and expedite access to PrEP and PEP by allowing pharmacists with special credentialing to dispense up to a 60-day supply without a prescription.[137] Additionally, the bill barred insurance companies from requiring prior authorization for PrEP coverage.

KEEPING CURRENT

The management of HIV infection continues to evolve. Additional important emerging data are in HIV prevention and cure. One example of a rapidly changing clinical landscape within the HIV treatment and prevention fields is the development of LA formulations of ART. With the development of newer, more potent ART, efficacious LA treatment strategies such as monthly intramuscular injections of CAB/RPV have the potential to dramatically simplify the provision of HIV treatment.[138] New technologies in development such as drug-eluting implants that administer up to a year of HIV PrEP offer promise beyond once-daily oral ART for HIV prevention.[139]

The overwhelming data presented at scientific meetings and in journals within this exciting and dynamic clinical environment have made staying informed about current issues and new developments a daunting task. As a result, many clinicians, even those actively caring for PLWH, remain cautious and often confused regarding therapeutic options.

New technologies for the dissemination of medical information are constantly evolving. The Internet has allowed clinicians worldwide to exchange ideas, teach new concepts, and obtain access to limited resources. In addition, many research centers, patient advocacy groups, and academic institutions have posted sites on the Internet that have resulted in access to large amounts of high-quality medical information. This new technology has also allowed, however, for the dissemination of incomplete, misleading, or inaccurate information. Therefore, clinicians must remain cautious and carefully evaluate the information obtained from various websites.

When evaluating the quality of a website, clinicians should look for a few basic standards.

- *Author qualifications.* Is the author qualified to write the article or perform the research? Is their affiliation or relevant credentials provided?
- *Attribution.* Are references provided to confirm statements? Is all relevant copyrighted information noted?
- *Currency.* When was the content posted? Is the website updated regularly?
- *Disclosure.* Who owns the website? Is there a conflict of interest between what is being posted and any commercial interest?

Any Internet site that fails to meet these basic competencies should be viewed with caution. In general, the most accurate and informative websites for HIV-specific information come from academic institutions, government organizations, medical societies, and patient advocacy groups. **Table 76-7** lists high-quality websites that

provide timely and accurate information. A periodic evaluation of these sites often provides sufficient information to stay up-to-date on current issues and controversies.

CONCLUSION

Given the significant advances in ART over the past 30 years, HIV-1 infection is now a manageable chronic disease for those who have access to ART. The pharmacologic management of HIV continues to rapidly evolve, but a basic understanding of viral pathogenesis and drug interactions provides a framework that can be used to evaluate new information as it becomes available. Although a cure is still out of reach, methods for preventing infection via TasP, PrEP, PEP, and through the prevention of perinatal transmission have become increasingly effective as alternative strategies for curbing the epidemic.

Opportunistic Infections in Patients Living With HIV

Emily L. Heil and Amanda H. Corbett

CORE PRINCIPLES		CHAPTER CASES
1	Acquired immunodeficiency syndrome (AIDS) is characterized by the gradual erosion of immune competence and the development of opportunistic infections (OIs) and malignancies. A decline in OIs and OI-related malignancies has been observed, which is associated with combined antiretroviral therapy (ART).	
2	*Pneumocystis jirovecii* pneumonia (PCP) should be treated with trimethoprim–sulfamethoxazole (TMP-SMX). Patients intolerant of sulfonamides should be treated with alternatives such as dapsone, atovaquone, or pentamidine. Steroids	**Case 77-1 (Questions 1–5)**

	should be used to treat patients with moderate-to-severe diseases. Primary prophylaxis with these agents is recommended for patients with CD4 counts <200.	
3	Toxoplasmosis typically occurs in patients with CD4 counts <100, and primary prophylaxis is indicated in these patients who are also *Toxoplasma* immunoglobulin G (IgG)-positive. Alternatives for prophylaxis include TMP-SMX, dapsone + pyrimethamine + leucovorin, and atovaquone ± pyrimethamine + leucovorin. Treatment options include sulfadiazine + pyrimethamine + leucovorin, clindamycin + pyrimethamine + leucovorin, and TMP-SMX.	**Case 77-2 (Questions 1–8)**
4	Cytomegalovirus (CMV) typically causes retinitis in persons living with HIV (PLWH) with CD4 counts <50. Primary prophylaxis is usually not indicated, and treatment options include intravenous (IV) ganciclovir, valganciclovir, IV foscarnet, and IV cidofovir.	**Case 77-3 (Questions 1–4)**
5	Cryptococcal meningitis occurs typically in patients with CD4 counts <50, and primary prophylaxis is not typically recommended. First-line treatment includes liposomal amphotericin B + flucytosine for induction therapy with subsequent addition of fluconazole for maintenance.	**Case 77-4 (Questions 1–8)**

6	*Mycobacterium tuberculosis* infects PLWH at any CD4 count, sometimes with an atypical presentation. Isoniazid for 9 months is the preferred regimen for latent tuberculosis (TB) in PLWH. Initial treatment in drug-susceptible TB is with rifampin (or rifabutin) + isoniazid + pyrazinamide + ethambutol.	**Case 77-5 (Question 1, 2) Case 77-6 (Question 1), and Case 77-7 (Question 1)**
7	*Mycobacterium avium* complex (MAC) can be localized to the lung or with disseminated infection in PLWH with CD4 counts <50. Primary prophylaxis is not indicated for patients on effective ART. First-line treatment for acute infection consists of clarithromycin (or azithromycin) + ethambutol ± rifampin (or rifabutin).	**Case 77-8 (Questions 1–6)**

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) is characterized by the gradual erosion of immune competence and the development of opportunistic infections (OIs). Since the advent of antiretroviral therapy (ART), which is the use of a combination of potent antiretroviral medications, AIDS-related mortality has declined in the United States.[1,2] The overall 5-year survival probability after the first OI diagnosis has increased dramatically from 7% in the pre-HAART (highly active antiretroviral therapy) to 65% in the ART era.[3] This decline in mortality has been associated with a decline in OIs and an increase in non-AIDS-related causes of mortality.[4] Persons living with HIV (PLWH) infection are susceptible to an array of diseases, but most OIs are caused by a few common pathogens, including

Pneumocystis jirovecii (*carinii*), cytomegalovirus (CMV), fungi, and mycobacteria.[5]

The revised classification system for human immunodeficiency virus (HIV) infection and expanded surveillance case definition for AIDS included stratification for the CD4 lymphocyte count, as well as subgrouping by clinical categories (see Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection, Table 76-1). These AIDS-defining OIs may also occur in asymptomatic PLWH.[5]

Natural History of Opportunistic Infections

DECLINE OF THE CD4 LYMPHOCYTE

Within the immune system, the CD4 lymphocyte functions as a "helper cell" that modulates the actions of the other key cellular components of the immune system. The eventual loss of CD4 lymphocytes is the underlying pathophysiology that leads to AIDS. (See Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection, and comprehensive immunology texts for a more detailed explanation of immune function and inflammation associated with HIV infection.) The infected CD4 lymphocyte can function normally for a time, but eventually becomes dysfunctional, as manifested by an abnormal response to soluble mitogens. It is this cellular functional deficit, compounded by the eventual decline in the absolute number of CD4 lymphocytes that leads to OIs and neurologic dysfunctions. The CD4 lymphocyte count declines gradually during several years in the untreated PLWH. The average rate of decline in CD4 lymphocyte cells (CD4 slope) is ~40 to 80 cells/μL/year in the absence of ART. An accelerated decline in the CD4 count occurs at 1.5 to 2 years, just before an AIDS-defining diagnosis.[6] Without therapy, the course of infection averages ~10 years from the time of initial infection to an AIDS-defining diagnosis.

The CD4 count dictates the need for OI prophylaxis, influences the differential diagnosis of the OI, and is an independent indicator of prognosis. For these reasons, the CD4 count has become a primary

surrogate marker of immune suppression and antiretroviral activity. HIV-1 ribonucleic acid (RNA) is the other clinical surrogate marker, most predictive of survival and antiretroviral activity.

OIs range from relatively minor events (eg, oral candidiasis or oral hairy leukoplakia) to sight-threatening episodes of CMV retinitis or life-threatening *Pneumocystis jirovecii* pneumonia (PCP). The risk of specific OIs varies with the degree of immunosuppression.[7] Asymptomatic patients with moderate immunosuppression (CD4 counts, 200–500) may become infected with herpes viruses and *Candida* species or develop pneumonia, enteric infection, and meningitis with more common pathogens. Massive destruction of the immune system occurs when the CD4 count drops <200, which increases the risk of opportunistic pathogens (eg, PCP), opportunistic tumors, wasting, and neurologic complications. With a CD4 count of 50 to 100, invasive candidiasis, cerebral toxoplasmosis, cryptococcosis, and various protozoal infections are observed. When the CD4 count falls <50, the patient is in an advanced immunosuppressed state, which is associated with non-Hodgkin lymphoma, CMV, and disseminated *Mycobacterium avium* complex (MAC; **Fig. 77-1**). Without treatment, the 5-year probability of survival associated with a CD4 count <100 is 43%, and the time to an AIDS-defining infection ranges from 18 to 24 months.[7,8]

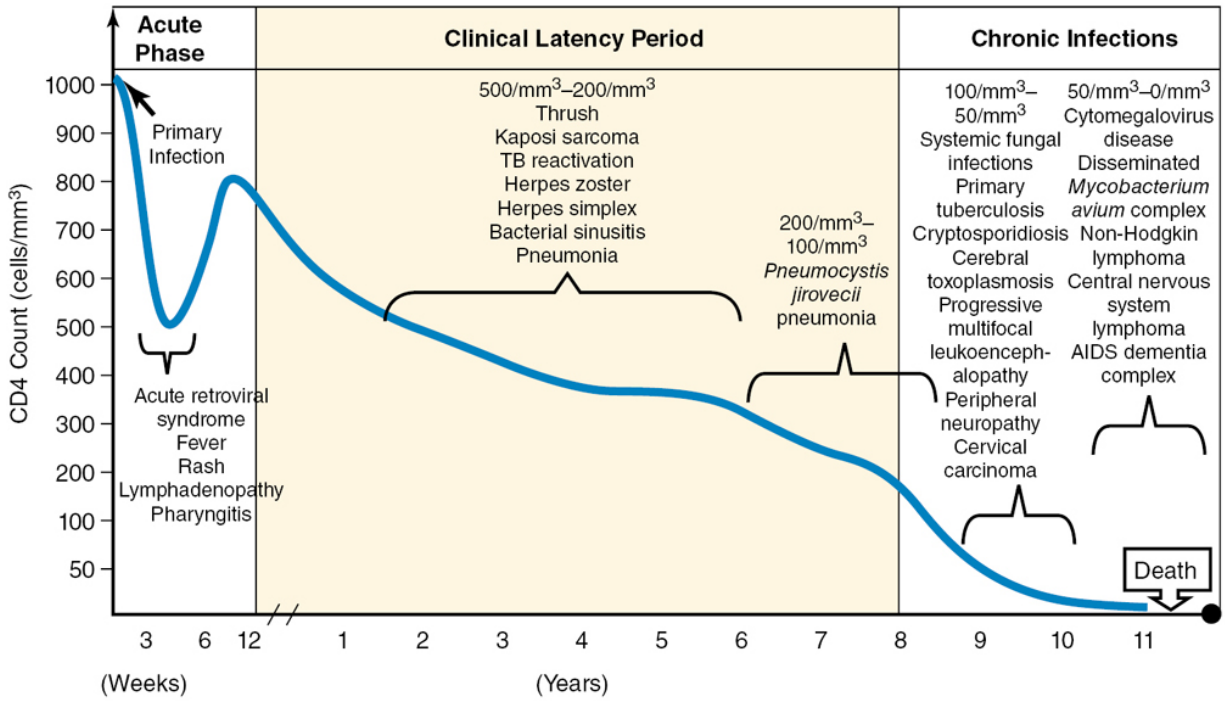

Figure 77-1 Natural history of CD4 cell count in the average patient living with HIV without antiretroviral therapy, from the time of HIV transmissions to death. (Illustration by Mary Van, PharmD.)

EFFECT OF OPPORTUNISTIC INFECTIONS ON VIRAL LOAD AND SURVIVAL

Acute OIs upregulate HIV replication, resulting in higher HIV-1 RNA concentrations in the plasma and lymphoid tissues of PLWH. This enhanced replication is presumably caused by antigen-mediated activation of HIV-1 replication in latently infected cells. To assess the impact of OIs on survival, data from a cohort of 2081 PLWH followed up (in the pre-ART era) for a mean of 30 months were analyzed.[9] CD4 counts and incidence of opportunistic disease were used as independent variables. These investigators found that PCP, CMV, MAC, esophageal candidiasis, Kaposi sarcoma (KS), non-Hodgkin lymphoma, progressive multifocal leukoencephalopathy (PML), dementia, wasting syndrome, toxoplasmosis, and cryptosporidiosis were independently associated with death.[9] In addition, data from a prospective longitudinal study of HIV infection in same-gender–loving males initiated in 1984 (Multicenter AIDS Cohort Study)

demonstrated that plasma HIV-1 RNA concentrations strongly predict the rate of decline in the absolute CD4 count and clinical progression to AIDS and death.[10] More recent investigations in the era of ART have demonstrated that CD4 count is the strongest prognostic factor in patients starting therapy.[8]

IMPACT OF ANTIRETROVIRAL AGENTS ON THE NATURAL HISTORY OF OPPORTUNISTIC INFECTIONS

Reduction in the incidence of opportunistic infections and death

The introduction of protease inhibitors, combination therapy, prophylaxis therapy, and improved medical care has reduced the incidence of OIs and death resulting from AIDS in patients living with HIV. ART generally refers to an antiretroviral regimen that can be expected to reduce the viral load in antiretroviral-naive patients to <50 copies/mL. A panel of experts convened by the U.S. Department of Health and Human Services recommended ART as the standard of care for all PLWH.[11] These potent antiretroviral agents and effective management of OIs have led to an improved quality of life and prolonged survival among PLWH in patients in the United States.[12]

CHANGES IN THE NATURAL HISTORY OF OPPORTUNISTIC INFECTIONS

OIs result from long-standing immunosuppression from HIV infection.[7] For example, before ART, ~40% of all patients with AIDS exhibited CMV retinitis, with the most cases occurring at CD4 counts <100. Since the implementation of ART, a decrease in the incidence and progression of CMV retinitis have been noted.[13],[14]

Ironically, ART has also been associated with a worsening or an unmasking of occult OIs in patients with an advanced stage of AIDS. When ART strengthens the immune system, inflammatory symptoms in response to infection are more clinically pronounced.[12] This syndrome has been referred to as *immune reconstitution inflammatory syndrome (IRIS)*. IRIS incidence is estimated to be

10% to 40% in patients starting ART, based primarily on retrospective observational data.[15–18] During IRIS, there is typically a rapid increase in CD4 lymphocytes; however, this does not represent fully functional cells, but rather an increase in memory subtypes.

The initiation of ART typically results in an increase in CD4 lymphocytes and a decrease in HIV RNA to undetectable levels. This initial increase in CD4 T cells after the initiation of therapy involves an increase in memory T cells with low proliferation and a decrease in functional or effector cells. As a result, infections that are present in tissues are allowed to proliferate once the immune system is recovering, allowing IRIS to occur.[19]

IMPROVEMENT IN OR RESOLUTION OF OPPORTUNISTIC INFECTIONS

With the initiation of ART, reports of improvement in or resolution of some OIs can occur.[20–24] These OIs include KS,[24] PML,[22] CMV,[13,14] microsporidiosis, cryptosporidiosis,[21] and molluscum contagiosum,[23] a viral infection caused by a member of the *Poxviridae* family. Furthermore, there are reports of restored immunity and clinical improvement in patients with chronic hepatitis B infection (not classified as a Centers for Disease Control and Prevention [CDC]-defined AIDS indicator condition) with the initiation of ART.[20] However, these infections were not eradicated, and, in some cases, improvement was only transient. Clinical resolution most likely results from immunologic improvement, and the protective immunity against OI is sustained only as long as ART remains effective.

Pharmacotherapeutic Management of Opportunistic Infections

Successful pharmacotherapeutic management of OIs requires an understanding of the natural history of HIV-associated OIs, including the recognition that OIs occur with declining CD4 lymphocyte counts, the clinical presentation of each disease, diagnostic techniques, and effective treatment and preventive strategies. Management issues,

complicated by multiple-drug therapy for OIs and HIV suppression, include adherence, toxicities, resistance, drug interactions, and cost. PLWH are usually less tolerant to drugs such as flucytosine, trimethoprim–sulfamethoxazole (TMP-SMX), and pyrimethamine; however, alternative agents are available to overcome these barriers to treatment.

A panel from the CDC, the National Institutes of Health (NIH), and the HIV Medicine Association of the Infectious Diseases Society of America (IDSA) maintain comprehensive guidelines for preventing exposure to opportunistic pathogens, preventing first episodes of the disease by chemoprophylaxis or vaccination (primary prophylaxis), and preventing disease recurrence (secondary prophylaxis). Current guidelines and any archived guidelines can be found at www.clinicalinfo.hiv.gov/guidelines.[12]

PRIMARY PROPHYLAXIS

Primary prophylaxis is defined as a therapy that is initiated before the appearance of an OI in high-risk asymptomatic persons to prevent the initial occurrence of an infection. Primary prevention of OIs is important, considering the inevitable immune depletion associated with chronic HIV infection.[25] PCP and MAC prophylaxis have significantly prolonged survival and delayed the onset of illness (see sections on Prophylaxis for both PCP and MAC).[26,27]

The guidelines strongly recommend primary prophylaxis against PCP, toxoplasmosis, latent tuberculosis infection (LTBI), and MAC (in patients not starting ART). Vaccinations to prevent *Streptococcus pneumoniae*, hepatitis B virus, hepatitis A virus, varicella-zoster virus (VZV), and influenza virus infection are generally recommended for all PLWH. Primary prophylaxis for fungal infections (*Cryptococcus neoformans* and *Histoplasma capsulatum*), CMV, and bacterial infections are not routinely recommended for most patients, except in unusual circumstances (**Table 77-1**).

Table 77-1
Primary Prophylaxis of Opportunistic Infections in HIV-Infected

Adults and Adolescents

	Preventive Regimens			
Pathogen	**Indication**	**First Choice**	**Alternatives**	**Discontinue Prophylaxis**
Strongly Recommended as Standard of Care				
Pneumocystis jirovecii (carinii)	CD4 count <200 or CD4 <14%	TMP-SMX, 1 DS PO daily or TMP-SMX 1 SS PO daily	TMP-SMX 1 DS tiw Dapsone 50 mg bid or 100 mg/day; dapsone 50 mg daily + pyrimethamine 50 mg qw + leucovorin 25 mg PO qw; aerosolized pentamidine 300 mg qm via Respirgard II® nebulizer, atovaquone 1500 mg PO daily; atovaquone 1500 mg PO + pyrimethamine 25 mg PO + leucovorin 25 mg PO daily	Patients on HAART with sustained CD4 >200 cells for ≥3 months may discontinue PCP prophylaxis. Reintroduce if CD4 >200.
Mycobacterium tuberculosis				
Isoniazid sensitive	+ Diagnostic test for TB with no evidence of active TB, no prior treatment *or* close contact with a person with active TB, with no evidence of active TB	Isoniazid 300 mg PO daily *or* isoniazid 900 mg PO biw × 9 months both with pyridoxine 50 mg PO daily ART recommended for all persons with HIV and LTBI	Rifapentine plus isoniazid 900 mg plus pyridoxine 50 mg once weekly for 12 weeks Rifampin 600 mg PO daily × 4 months	
Drug-resistant TB	Same; high probability of exposure to isoniazid-resistant TB	Choice of drugs requires consultation with public health authorities.	None	
Toxoplasma gondii	IgG antibody to *Toxoplasma* and CD4 count <100	TMP-SMX, 1 DS PO daily	TMP-SMX, 1 SS PO daily; TMP-SMX 1 DS PO tiw; dapsone 50 mg PO daily + pyrimethamine 50 mg PO qw + leucovorin 25 mg PO qw; dapsone 200 mg PO qw + pyrimethamine 75 mg PO qw + leucovorin 25 mg PO qw; atovaquone 1500 mg PO daily with or without pyrimethamine 25 mg PO daily + leucovorin 10 mg PO daily	Patients on HAART with sustained CD4 >200 for ≥3 months may discontinue toxoplasmosis prophylaxis. Restart if CD4 >100–200.
MAC	CD4 <50 in those who are not on fully suppressive ART after ruling out disseminated MAC	Azithromycin, 1200 mg PO qw; clarithromycin 500 mg PO bid; azithromycin 600 mg PO biw	Rifabutin, 300 mg PO daily	Patients on HAART with sustained CD4 >100 for ≥3 months may discontinue MAC prophylaxis. Restart if CD4 >50.
VZV	Pre-exposure prevention: Patients with CD4 ≥200 who have not been vaccinated, have no history of varicella or herpes zoster, or who are seronegative for VZV Postexposure prevention: Significant exposure to chicken pox or shingles for patients who are susceptible	Pre-exposure: Primary varicella vaccination, two doses administered 3 months apart Postexposure prevention: VZIG 125 IU per 10 kg (maximum of 635 IU) IM administered 96 hours after exposure		

	Preventive Regimens			
Pathogen	**Indication**	**First Choice**	**Alternatives**	**Discontinue Prophylaxis**
Usually Recommended				
Streptococcus pneumoniae	Regardless of CD4 count followed by:	PCV13 0.5 mL × 1 Followed by: PPV23 0.5 mL IM at least 8 weeks after PCV13 if CD4 ≥200 If CD4 <200, PPV23 can be offered at least 8 weeks after receiving PCV13 or can wait until CD4 ≥200	None	
HBV	All susceptible (anti-HBc-negative) patients	Hepatitis B vaccine series (depends on the vaccine used)	None	
HPV	Females and males ages 13–26 years	HPV recombinant vaccine 9 valent at 0, 1–2, and 6 months		
Influenza virus	All patients (annually before influenza season)	Inactivated influenza vaccine per recommendation for the season (note, live attenuated influenza vaccine is contraindicated in all PLWH)		
HAV	All susceptible (anti-HAV-negative) patients at increased risk for HAV or patients with chronic liver disease (including HBV or HCV) or who are injection drug users	Hepatitis A vaccine; two doses	None	
Not Recommended for Most Patients; Indicated for Use Only in Unusual Circumstances				
Histoplasma capsulatum	CD4 count ≤150 and at high risk owing to endemic geographic areas	Itraconazole 200 mg PO daily	None	
Coccidioidomycosis	Positive IgM or IgG serologic test in patients in an endemic area with CD4 <250	Fluconazole 400 mg daily	None	

ART, antiretroviral therapy; bid, twice a day; biw, twice weekly; DS, double strength; HAART, highly active antiretroviral therapy; HAV, hepatitis A virus; HBc, hepatitis B core; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; IgG, immunoglobulin G; IgM, immunoglobulin M; IM, intramuscularly; IU, international units; LTBI, latent tuberculosis infection; MAC, *Mycobacterium avium* complex; PCP, *Pneumocystis jirovecii* pneumonia; PCV13, 13-valent pneumococcal conjugate vaccine; PLWH, persons living with HIV; PO, orally; PPV23, 23-valent pneumococcal polysaccharides vaccine; qm, monthly; qw, weekly; SS, single strength; tiw, three times a week; TMP-SMX, trimethoprim–sulfamethoxazole; VZIG, varicella-zoster immune globulin; VZV, varicella-zoster virus.

America. https://clinicalinfo.hiv.gov/en/guidelines/adult-and-adolescent-opportunistic-infection/.

Discontinuation of primary prophylaxis therapy

ART has diminished the incidence of several OIs.[14,21,24] Therefore, it may be possible to discontinue prophylactic OI therapy when CD4 counts rise above the threshold associated with the risk of infection. These data have been particularly encouraging in patients who had PCP prophylaxis discontinued with an increase in CD4 counts.[12] In one observational PCP prophylaxis study, no episodes of PCP were observed after the discontinuation of primary and secondary PCP prophylaxis.[28] These studies suggest that patients who respond to ART with a sustained increase in CD4 count can have their primary prophylaxis safely discontinued. The OI prophylaxis guidelines suggest that primary PCP prophylaxis may be discontinued for patients on ART when the CD4 count is >200 for at least 3 months. In addition, the guidelines suggest discontinuing primary prophylaxis for toxoplasmosis when the CD4 count increases to >200 for at least 3 months.[12]

ACUTE THERAPY

Prompt diagnosis and immediate initiation of therapy are essential for the management of acute infections. Most common OIs can be classified into one of two groups. The first group consists of infections that can be treated by conventional or investigational agents. These include PCP, TB, cryptococcosis, CMV, MAC, and histoplasmosis. Treatment may result in either effective or moderately effective resolution. These infections may recur if chronic suppressive or secondary prophylaxis is discontinued without an accompanying elevation in the CD4 count and viral load suppression. The second group includes pathogens for which no therapeutic regimen is currently effective. These include cryptosporidiosis, microsporidiosis, and PML.

SECONDARY PROPHYLAXIS OR CHRONIC SUPPRESSIVE THERAPY

Secondary prophylaxis is used to prevent the recurrence of an OI once the patient has developed signs and symptoms of active infection. In some cases, secondary prophylaxis regimens can be discontinued after patients achieve a certain CD4 level. The OI guidelines strongly recommend secondary prophylaxis for PCP, toxoplasmosis (reduced dosage), MAC, CMV, and infections caused by endemic fungi and *C. neoformans.*[12]

Discontinuation of secondary prophylaxis or chronic suppressive therapy

The OI guidelines recommend discontinuing primary or secondary prophylaxis for certain pathogens with ART-related increases in CD4 count to specified threshold levels.[12] Criteria for discontinuing chemoprophylaxis are based on specific clinical studies and vary by duration of CD4 count increase and duration of treatment of the initial episode of disease (in the case of secondary prophylaxis).

Secondary PCP prophylaxis may be discontinued among patients whose CD4 counts have increased to >200 for >3 months while on ART. Secondary prophylaxis for disseminated MAC may be discontinued among patients who have completed 12 months of MAC therapy, have no signs or symptoms of MAC, and have had a CD4 count of >100 for ≥6 months in response to ART. Similarly, secondary prophylaxis for toxoplasmosis may be discontinued in patients who have completed initial therapy, have no signs or symptoms of infection, and have had CD4 counts of >200 for >6 months in response to ART. Patients with cryptococcal meningitis can discontinue prophylaxis after completing their initial therapy if they have received at least 1 year of maintenance therapy, remain asymptomatic, and have a CD4 count >100 for at least 3 months on ART. Maintenance therapy for CMV can be discontinued safely in patients who have maintained a CD4 count of >100 for >6 months on ART.[12,14] The decision to stop CMV prophylaxis should be made in consultation with an ophthalmologist and is influenced by factors

such as the magnitude and duration of CD4 increases and viral load suppression, anatomic location of retinal lesions, and vision in the contralateral eye.

Although there are considerable data concerning the discontinuation of primary and secondary prophylaxis, there are no data regarding restarting prophylaxis if the CD4 count decreases again to levels at which the patient is likely to again be at risk for OIs. For primary prophylaxis, the same CD4 count threshold for stopping or restarting therapy is recommended. For PCP prophylaxis, the current guidelines use a CD4 count of 200 as the threshold for restarting both primary and secondary prophylaxis. For toxoplasmosis, the CD4 threshold is 100 to 200, and for MAC, it is 50 in patients not on suppressive ART.[12]

PNEUMOCYSTIS JIROVECII PNEUMONIA

As an indication of the relative obscurity of this organism, no comprehensive text on PCP was available until 1983.[29] Since that time, this organism has been reclassified from a protozoan to a fungus on the basis of ribosomal RNA sequence comparisons. The morphologic resemblance of *P. carinii* to a protozoan has led to its life cycle being described as a cyst form, with up to eight sporozoites per cyst. The trophozoite or extracystic form has different staining characteristics (ie, it does not stain with Toluidine Blue O or Grocott-Gomori stains) compared with the cyst or sporozoites. In addition, current literature refers to PCP as *P. jirovecii* as opposed to the original terminology of *Pneumocystis carinii.* The former species is the one responsible for infectivity in humans. *P. jirovecii* pneumonia is the second leading OI affecting PLWH in the United States.[2] Hospitalizations and hospital mortality for AIDS-associated PCP have decreased significantly in the past 20 years; however, there has been a shift in the overall population at risk for PCP over time, with a greater proportion of patients with PCP who are Black, female, or from the southern region of the United States.[30]

Clinical Presentation

CASE 77-1

QUESTION 1: J.R. is a 38-year-old, HIV-seropositive male who was diagnosed 5 years ago when he had an outbreak of herpes zoster. He has not been on any ART or prophylaxis since his diagnosis because of ongoing socioeconomic challenges. J.R. developed a mild, nonproductive cough that has persisted for the past 4 weeks. He has also had a low-grade fever, but denies any chills or pleuritic chest pain. His chest radiograph demonstrates a diffuse, symmetric, interstitial infiltrate. Arterial oxygen partial pressure (Pa_{O_2}) is 80 mm Hg. His last CD4 count ~3 months ago was 180 cells/μL, and his viral load was 60,000 copies/mL, After hypertonic saline nebulization for sputum induction and subsequent bronchoalveolar lavage, examination of the specimens with the modified Giemsa stain revealed both intracystic bodies and extracystic trophozoites.

How is the clinical presentation of J.R. consistent with PCP?

The clinical features of PCP in patients with AIDS differ from those of patients with no AIDS in that a more subtle onset, with mild fever, a cough, tachypnea, and dyspnea, is typically seen in PLWH.[12] J.R.'s low-grade fever and mild, nonproductive cough of 4 weeks' duration are consistent with this description of PCP. His history of HIV infection and the finding of trophozoites on Giemsa stain further support a diagnosis of PCP. The characteristic diffuse interstitial pulmonary infiltrates on J.R.'s chest radiograph are consistent with PCP. Limited data exist with regard to the latent state of *P. jirovecii* after host infection. Some investigators hypothesize that most persons are asymptomatic unless the host immune system becomes impaired. Others believe that the infection is caused by reinfection as opposed to reactivation.[31]

Antimicrobial Selection

CASE 77-1, QUESTION 2: A diagnosis of PCP is made and J.R. agrees to be treated. What patient factors are important to consider when selecting an

antimicrobial? What would be a reasonable drug for J.R., and how might his course of PCP be monitored?

The treatment of acute PCP is determined by the degree of clinical severity on presentation. The arterial oxygen status on presentation is an important indicator of overall outcome. Key factors to consider when initiating therapy for PCP include arterial blood gas findings, whether it is an initial or a repeat episode of PCP, the need for parenteral therapy, and a prior history of adverse drug reactions or hypersensitivity. Concomitant therapy must also be considered.

Patients with PCP often can be classified as having mild, moderate, or severe disease, based on their oxygenation. Patients with mild PCP often have a room air alveolar-arterial (A-a) oxygen gradient of <35 or Pa_{O_2} >70 mm Hg, and patients with moderate or severe disease have an A-a >35 mm Hg or Pa_{O_2} <70 mm Hg. With the advent of corticosteroid use for moderate-to-severe cases of PCP (discussed later), it is useful to calculate the A-a gradient or Pa_{O_2}. The A-a gradient (normal range, 5–15 mm Hg) can be calculated as $P_{IO_2} - (1.25 \times Pa_{CO_2}) - Pa_{O_2}$, where P_{IO_2} is the partial pressure of inspired oxygen (150 mm Hg in room air), and Pa_{CO_2} and Pa_{O_2} are arterial levels of CO_2 and O_2, respectively, expressed in mm Hg.

Several other clinical tests have been used to identify and monitor PCP. The lactate dehydrogenase concentration in serum or bronchoalveolar lavage fluid has been used to aid in diagnosis, monitor therapy, and to predict the outcome of PCP. However, it is a nonspecific value and should not be used alone. Chest radiographs also vary with PCP. The most common picture is one of bilateral diffuse interstitial pneumonitis, but atypical patterns, such as pleural effusion, cavities, pneumatoceles, and nodules, may also occur. A normal chest radiograph is associated with improved clinical outcome.

The natural course of PCP among untreated PLWH is progressive dyspnea and hypoxemia. Increasing patient age, a subsequent episode of PCP, low hemoglobin, low partial pressure of oxygen

breathing room air, the presence of medical comorbidity, and pulmonary KS are all early predictors of mortality from PCP at hospital admission.[32] The treatment of PCP in patients with AIDS (compared with non-PLWH) indicates that a longer duration of therapy is needed.[29] Some patients may experience worsening hypoxemia during the first 3 to 5 days after the treatment is initiated. This period of clinical worsening is least tolerated by those patients with moderate-to-severe PCP (Pa_{O_2} ≤70 mm Hg). In patients who are extremely sick, this period may lead to respiratory failure and the need for intubation. Although many would associate the need for intensive care unit admission as a poor prognostic factor, many patients do well despite the need for mechanical ventilation and IV antibiotics. In light of the role of corticosteroids, patients with PCP and respiratory failure may be viewed as manageable if treated aggressively (**Table 77-2**).

Table 77-2
Treatment of *Pneumocystis jirovecii* Pneumonia

Regimen	Dose	Route	Adverse Effects/Comments
Approved			
TMP-SMX	15–20 mg/kg TMP (75–100 mg/kg SMX) daily administered IV or PO every 6–8 hours or two DS tablets tid	IV, PO	Hypersensitivity, hyperkalemia, rash, fever, neutropenia ↑LFTs, and nephrotoxicity (15 mg/kg/day preferred to 20 mg/kg/day because of reduced toxicity)
Pentamidine isethionate	4 mg/kg IV daily for 60–90 minutes × 21 days	IV	Pancreatitis, hypotension, hypoglycemia, hyperglycemia, and nephrotoxicity
Atovaquone[a]	750 mg bid with meals × 21 days (suspension)	PO	Headache, nausea, diarrhea, rash, fever, and ↑LFTs
TMP[a] + dapsone	15 mg/kg/day	PO	Pruritus, GI intolerance, and bone marrow suppression
	100 mg/day × 21 days	PO	Methemoglobinemia and hemolytic anemia (contraindicated in G6PD deficiency)
Clindamycin + primaquine	600 mg IV every 8 hours or 300–450 mg PO every 6 hours	PO or IV	Rash and diarrhea
	15–30 mg (base) daily × 21 days	PO	Methemoglobinemia and hemolytic anemia (contraindicated in G6PD deficiency)
Prednisone	Within 72 hours of anti-*Pneumocystis* therapy 40 mg every 12 hours × 5 days, then 40 mg daily × 5 days, then 20 mg/day × 11 days	PO	Initiation in patients with moderately severe or severe disease (Pa_{O_2} <70 mm Hg or A-a gradient ≥35 mm Hg) in combination with one of the abovementioned antibiotic regimens

A-a, alveolar-arterial gradient; bid, twice a day; DS, double strength; GI, gastrointestinal; G6PD, glucose-6 phosphate dehydrogenase; IV, intravenous; PO, oral; Pa_{O_2}, arterial partial pressure of oxygen; LFTs, liver function tests; tid, three times a day; TMP-SMX, trimethoprim–sulfamethoxazole.

[a]Used only in mild-to-moderate *Pneumocystis jirovecii* pneumonia.

TRIMETHOPRIM–SULFAMETHOXAZOLE

The decision to hospitalize a patient is based on the severity of his or her illness. Patients who present with mild PCP with reasonable oxygenation and without evidence of clinical deterioration can be managed as outpatients. Patients with reasonably good gas exchange (ie, Pa_{O_2} >70 mm Hg) but with signs of clinical deterioration most often are admitted to the hospital and given oxygen by nasal cannula and are usually started on IV TMP-SMX (15–20 mg/kg/day TMP) for 21 days.[12,33] The dosing of IV TMP-SMX must be modified in patients with renal dysfunction. TMP reversibly inhibits dihydrofolate reductase, and sulfamethoxazole competes with para-aminobenzoic acid in the production of dihydrofolate, synergistically blocking thymidine biosynthesis.

TMP-SMX is the drug of choice for PCP unless the patient has a history of life-threatening intolerance. In the treatment of PCP, TMP-SMX is either as effective as or superior to all alternative agents. A good response may be expected in >70% of patients receiving TMP-SMX. TMP-SMX is often prescribed orally (PO) because of its high bioavailability. The usual dose is 15 mg/kg (dosed by the TMP component) divided every 8 hours for 21 days. Because one double-strength tablet of TMP-SMX contains 160 mg TMP plus 800 mg SMX, a standard regimen is two double-strength tablets three times per day (tid; or every 8 hours).

Although the TMP-SMX regimen is very efficacious, 25% to 50% of patients may be intolerant. Adverse effects include an erythematous, maculopapular, morbilliform rash, and, less commonly, severe urticaria, exfoliative dermatitis, and Stevens–Johnson syndrome. Gastrointestinal (GI) intolerance (nausea, vomiting, and abdominal pain) is common.[12] Hematologic side effects may include leukopenia, anemia, and thrombocytopenia. Neurologic toxicities, acute kidney injury, hyperkalemia, and hepatitis may also occur. Most patients who exhibit a mild hypersensitivity (skin rash) reaction can be managed with antipruritics or antihistamines without discontinuation of TMP-SMX. In some patients with mild hypersensitivity reactions, the agent can be

restarted after the rash has resolved, using gradual dosage escalation or rapid oral desensitization to reduce adverse effects.[34] Patients with severe adverse reactions should be switched to another agent rather than being rechallenged with this drug (see also Chapter 32, Drug Hypersensitivity Reactions).

Because J.R. seems to have a mild-to-moderate case of PCP (PaO_2, 80 mm Hg), has not previously experienced an episode of PCP, and has no history of adverse effects to TMP-SMX, an outpatient course of TMP-SMX would be reasonable.

ALTERNATIVES TO TRIMETHOPRIM–SULFAMETHOXAZOLE

CASE 77-1, QUESTION 3: J.R. experienced exfoliative dermatitis on day 7 of TMP-SMX treatment. What other drugs could be prescribed to treat his PCP?

Because J.R. presents with a serious adverse effect to TMP-SMX, it should be discontinued, and he should not be rechallenged or desensitized. Instead, he should be treated with an alternative regimen (Table 77-2).

Atovaquone suspension, 750 mg twice a day (bid), is available for the treatment of mild-to-moderate PCP. Atovaquone interrupts protozoan pyrimidine synthesis and demonstrates activity against *P. jirovecii* and *Toxoplasma gondii* in animal models. Atovaquone is approved by the U.S. Food and Drug Administration (FDA) for the treatment of mild-to-moderate PCP in patients intolerant of TMP-SMX. Atovaquone is also an alternative for primary and secondary prophylaxis for both PCP and toxoplasmosis.[12] Atovaquone is well tolerated compared with other PCP therapies. Adverse effects include rash, fever, elevated liver function tests (LFTs), and emesis. Atovaquone is safer, but less effective, than is TMP-SMX in patients with mild-to-moderate PCP.[35] When compared with IV pentamidine in the treatment of mild-to-moderate PCP, atovaquone and pentamidine were equally efficacious; however, pentamidine was significantly more toxic.[36] Most atovaquone studies were performed using the moderately absorbed oral tablets; reformulation of this drug as a

suspension has improved bioavailability by at least 30%, although patients may find the taste and texture unpleasant. Concomitant administration of fatty foods with atovaquone doubles the absorption.

An oral regimen of dapsone plus TMP is another alternative to TMP-SMX. Dapsone–TMP can be used to treat mild-to-moderate PCP in patients intolerant of TMP-SMX. Dapsone is a sulfone antimicrobial that is used for leprosy. Although monotherapy (200 mg/day) with dapsone is ineffective for the treatment (not prophylaxis) of PCP, the addition of TMP (20 mg/kg/day) to dapsone (100 mg/day) is an effective alternative regimen.[37] In a small comparative trial of TMP–dapsone versus TMP-SMX, the response rates of 93% and 90% were observed, respectively.[38] When dapsone is coadministered with TMP, the resulting plasma concentrations for both drugs are higher than when either drug is taken alone. In combination with TMP, a pyrimidine, synergistic inhibition of folic acid synthesis occurs.[39] Dapsone–TMP should not be used in patients with sulfonamide allergy with a history of type I hypersensitivity reaction, toxic epidermal necrolysis, or Stevens–Johnson syndrome. Dapsone is associated with hematologic toxicities, including hemolytic anemia, methemoglobinemia, neutropenia, and thrombocytopenia. Patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency cannot detoxify hydrogen peroxide and are at an increased risk for hematologic toxicity from dapsone.

Success rates of 70% to 100% have been reported with clindamycin (600 mg IV every 6 hours or 600 mg PO tid given in conjunction with 30 mg/day of primaquine base). Although skin rashes are common with this combination, these often subside with continued therapy. Some patients experience toxicities (fever, rash, granulocytopenia, and methemoglobinemia), requiring discontinuation.[40–42] As with dapsone, before starting primaquine, patients should be screened for G6PD deficiency. Patients who test positive for G6PD deficiency are at risk for developing hemolytic anemia.

A double-blind efficacy and toxicity study of 181 patients with mild-to-moderate PCP compared three oral drug regimens: TMP-SMX

versus dapsone–TMP versus clindamycin–primaquine. The doses of TMP-SMX and dapsone–TMP were weight based, and the dosage of clindamycin–primaquine was 600 mg clindamycin tid and primaquine 30 mg/day. All patients with moderately severe PCP (A-a oxygen gradient >45) were treated with prednisone (40 mg bid for 5 days, then once daily for 3 weeks). Rash was the most frequent dose-limiting toxicity (TMP-SMX, 19%; dapsone–TMP, 10%; and clindamycin–primaquine, 21%). Hematologic toxicities were observed more frequently in the clindamycin–primaquine arm. Elevated LFTs (five times above baseline) were more frequent in the TMP-SMX arm. The clindamycin–primaquine group demonstrated better quality of life scores at day 7, but by day 21, these differences became less significant.[37] TMP-SMX, dapsone–TMP, and clindamycin–primaquine demonstrated equal efficacy in patients with mild-to-moderate PCP.

A last-line option for acute PCP is IV pentamidine isethionate. The mechanism of action is unknown, but it may be related to interference with oxidative phosphorylation, inhibition of nucleic acid biosynthesis, or interference with dihydrofolate reductase. Pentamidine is generally more toxic than is TMP-SMX.[43] In a 5-year review of 106 courses of IV pentamidine, 76 (72%) patients had adverse reactions (nephrotoxicity, dysglycemia, hepatotoxicity, hyperkalemia, and hyperamylasemia). Drug discontinuation occurred in 31 of the 174 adverse drug events reported in the study. Nephrotoxicity and hypoglycemia were the most common causes of drug discontinuation. Nephrotoxicity occurred in 25% to 50% of the patients with dehydration and concurrent nephrotoxic drugs among the risk factors. Hypoglycemia was noted in 5% to 10% of patients after 5 to 7 days of treatment or several days after discontinuation of treatment. Hyperglycemia is a consequence of decreased β-cells and results in diabetes mellitus in 2% to 9% of patients. Other less common adverse effects and toxicities include thrombocytopenia, orthostatic hypotension, ventricular tachycardia, leukopenia, nausea, vomiting, abdominal pain, and anorexia.[43] Nebulized pentamidine should not be considered as an alternative to IV pentamidine for the treatment of PCP.[44]

J.R. should be hospitalized to better manage his severe adverse reaction and to complete his treatment of PCP. Because of his severe reaction to TMP-SMX, dapsone–TMP should not be administered because dapsone is a sulfone with a risk of cross-reactivity in patients with severe sulfonamide allergies. IV pentamidine is an option for J.R., but its toxicity suggests that it should be reserved for patients with more severe PCP presentation. Atovaquone is a reasonable option for patients with mild PCP who are intolerant of TMP-SMX and have no evidence of GI dysfunction, but it is not as effective as TMP-SMX or IV pentamidine. Clindamycin–primaquine is as efficacious as TMP-SMX for the treatment of mild-to-moderate PCP and can be administered PO. Consequently, it is the drug of choice in this patient.

The decision was made to start J.R. on oral clindamycin–primaquine for his mild-to-moderate PCP. J.R. tested negative for G6PD deficiency and was treated with clindamycin–primaquine for 14 days, completing a 21-day course of PCP therapy (Table 77-2).

Initiation of Corticosteroids

Case 77-1, Question 4: Should J.R. receive corticosteroid therapy with PCP treatment? If so, when should corticosteroids be initiated, and what would be a reasonable regimen for patients with PCP?

Corticosteroids have an important role in the management of patients with acute PCP who are clinically ill and have a low Po_2 (<70 mm Hg) or an A-a oxygen gradient >35.[12] Many patients who are started on PCP therapy have an acute period of clinical deterioration, which may be associated with an acute inflammatory reaction to the rapid killing of *Pneumocystis.* Particularly among patients with moderate-to-severe PCP (A-a oxygen gradient ≥35 mm Hg or Pao_2 <70 mm Hg on room air), the use of prednisone during the first 72 hours of treatment may prevent fatal acute deterioration.[45] Corticosteroids may also have some benefits in patients exhibiting acute respiratory failure after 72 hours of

conventional PCP therapy.[46] The recommended dose of prednisone is 40 mg given PO bid for 5 days, then 40 mg/day for 5 days, and then 20 mg/day for 11 days, for a total of 21 days.[47] Patients requiring IV corticosteroids may receive methylprednisolone at 75% of the prednisone dose. The major concern using glucocorticoids is the activation of latent infections (such as TB) or exacerbation of an active undiagnosed condition (especially fungal infections). However, the beneficial role of corticosteroids as adjunctive therapy outweighs the relative risk of short-term steroid use in this population.[48] More common side effects of short-term corticosteroids include hyperglycemia, ulcerative esophagitis, increased appetite, weight gain, sodium and fluid retention, headache, and elevated LFTs. Corticosteroids should be used with caution in the presence of uncontrolled diabetes, active GI bleeding, and uncontrolled hypertension.

Considering his mild hypoxemia (Pa_{O_2}, >70 mm Hg), J.R. is not a candidate for corticosteroid therapy.

Prophylaxis

Case 77-1, Question 5: J.R. was hospitalized and responded well to treatment. He now is a candidate for secondary prophylaxis. What secondary prophylaxis would be a good choice for J.R. when he is discharged from the hospital?

The early recognized efficacy of TMP-SMX prophylaxis[41] led to the eventual widespread application of prophylaxis and the development of guidelines for PCP prophylaxis (Table 77-2).[12] PLWH not receiving ART or *Pneumocystis* prophylaxis were associated with a PCP prevalence of 8.4%, 18.4%, and 33.3% at 6, 12, and 36 months, respectively, in patients with a CD4 count of <200.[49] These data have formed the basis on which patients receive PCP prophylaxis. In addition to patients with CD4 counts of <200, other patients at risk for PCP include those with a CD4 count of <14%, a history of an AIDS-defining illness, a history of oropharyngeal candidiasis, and

possibly those with CD4 counts of 200 to 250.[12] J.R. refused primary prophylaxis and developed PCP. Secondary prophylaxis is necessary for J.R. to prevent recurrence and should be continued for life or until immune reconstitution occurs as a result of ART.

The same agents and dosing schedules are recommended for primary (before an acute event) and secondary (after an acute event) prophylaxis of PCP.[12] TMP-SMX, one double-strength tablet daily, is the most efficacious prophylactic regimen; a single-strength tablet given daily is less toxic and nearly as efficacious. Patients with a history of non–life-threatening rash or fever caused by TMP-SMX may benefit from rechallenge with the original (or half) dose, or a dose escalation technique (desensitization regimen). Desensitization is preferred to switching to an alternative agent and is more successful than is the direct rechallenge method.[50] Desensitization involves initiating very low doses of TMP-SMX and gradually increasing to the maximum dose over the course of days to weeks. In addition, patients who develop PCP while receiving prophylactic doses of TMP-SMX usually respond to full therapeutic doses for acute therapy. However, J.R. had a life-threatening reaction to TMP-SMX and should not be rechallenged or desensitized, and another agent should be chosen for prophylaxis.

The alternative agents used for prophylaxis include dapsone, dapsone plus pyrimethamine (with leucovorin), atovaquone suspension, and aerosolized pentamidine administered by the Respirgard II® nebulizer (Table 77-2). TMP-SMX confers additional protection against toxoplasmosis and certain bacterial infections. Regimens containing dapsone plus pyrimethamine or atovaquone with or without pyrimethamine also protect against toxoplasmosis.[12] Although yet to be confirmed in clinical trials, other options include oral clindamycin–primaquine, intermittently administered IV pentamidine, oral pyrimethamine–sulfadiazine, and aerosolized pentamidine administered by other nebulizing devices.[12] TMP-SMX is more efficacious than is dapsone or aerosolized pentamidine in the prevention of PCP.[51]

Extrapulmonary (eg, lymph nodes, spleen, liver, bone marrow, adrenal gland, and GI tract) *P. carinii* has been noted in patients

receiving inhaled pentamidine prophylaxis,[52] a finding rarely observed with IV administration. In addition, aerosolized pentamidine alters the usual chest radiograph findings associated with PCP, potentially complicating the diagnosis of this disease. Upper lobe infiltrates, cystic lesions, pneumothoraces, cavitary lesions with nodular infiltrates, and pleural effusions have been associated with aerosolized pentamidine prophylaxis.

The guidelines for primary prophylaxis suggest that prophylactic antimicrobial therapy can be discontinued when CD4 counts rise above the threshold associated with a risk for infection (ie, >200 for PCP).[12] Many studies support the practice of discontinuing secondary PCP prophylaxis in patients whose CD4 counts have increased to >200 for at least 3 months.[12] A European cohort study found that primary PCP rates were very low in patients with CD4 counts of 101 to 200 cells/μL and a viral load of <400 copies/mL regardless of prophylaxis, indicating that discontinuation of prophylaxis may be safe in patients with a CD4 count >100 cells/μL who are on effective antiretrovirals.[53] The guidelines recommend that prophylaxis be reintroduced if the CD4 count decreases to <100 or if CD4 100 to 200 and HIV RNA is detectable.[12] J.R. responded well to his PCP treatment with clindamycin–primaquine in the hospital. However, because this regimen is unproved for secondary prophylaxis, it cannot be recommended. Considering his severe intolerance to TMP-SMX, the best selection would be atovaquone suspension.

TOXOPLASMA GONDII ENCEPHALITIS

Clinical Presentation

CASE 77-2

Question 1: W.O. is a 40-year-old male discovered to be HIV positive during admission to a detoxification program for alcohol and heroin dependency. W.O. presented to the HIV clinic with esophageal candidiasis, a CD4 count of 60 cells/μL (normal, ~1000 cells/μL), a viral load of 150,000 copies/mL, and a *Toxoplasma* IgG titer of 1:256. W.O. was started on ART. He remained well until 2 years later when he presented to the emergency department reporting two seizures in the past 24 hours. His home medications at that time included daily emtricitabine, tenofovir alafenamide, dolutegravir, and inhaled pentamidine 300 mg monthly, although the patient reported nonadherence for the past 6 months. His temperature was 100.1 °F (37.83 °C), and he was observed to have difficulty walking. His CD4 count is 90 cells/μL (previously 230 cells/μL), viral load is 70,000 copies/mL (previously 200), and white blood cell (WBC) count is 4200 cells/L (normal, 3800–9800). A magnetic resonance imaging (MRI) of the head reveals several ring-shaped lesions in the brainstem. *Toxoplasma* encephalitis is presumptively diagnosed.

Should W.O. be isolated from other patients and health care workers to prevent the spread of this organism?

T. gondii is a parasitic protozoan that can infect people and is spread by environmental factors, such as the consumption of raw or undercooked meats and contact with cat feces. Immunocompetent persons infected with *T. gondii* may develop mild symptoms resembling infectious mononucleosis. However, these symptoms are generally transient and not associated with significant sequelae in patients who are immunocompetent (except in pregnant females). Recrudescent disease from *T. gondii* is problematic in patients with a suppressed cellular immune system, including those infected with HIV. Any PLWH infected with *T. gondii* is at risk for developing clinical disease, particularly at CD4 counts <100, as illustrated by W.O.[12] W.O. presents with encephalitis (an inflammation of the brain or brainstem), the most frequent manifestation of *T. gondii* in PLWH.

All PLWH should be tested for IgG antibody to *T. gondii* after HIV diagnosis to detect latent infection. In the United States, as many as 70% of healthy adults are seropositive to *Toxoplasma.* The prevalence of *Toxoplasma* encephalitis among patients who are HIV positive varies depending on the geographic region. In the United States, only 3% to 10% of patients with AIDS actually develop encephalitis. In countries such as France, El Salvador, and Tahiti,

where uncooked meat commonly is ingested, seropositivity is >90% by the fourth decade of life. *Toxoplasma* encephalitis may develop in as many as 25% to 50% of patients with AIDS in these countries.[54]

The two major routes of transmission of *Toxoplasma* to humans are oral and congenital. W.O. need not be isolated from other patients and health care workers. PLWH should be advised not to eat raw and undercooked meat (internal temperature of meat should be at least 165 °F–170 °F), especially patients who are IgG negative for *T. gondii.* Patients should wash their hands after touching uncooked meats and soil, and fruits and vegetables must be washed before eating. PLWH should avoid stray cats, keep their cats inside, and change the litter box daily. If no one else is available to change the litter box, patients should wash their hands thoroughly afterward.[12]

Diagnosis

Case 77-2, Question 2: Is there sufficient clinical evidence to establish a presumptive diagnosis of *Toxoplasma* encephalitis in W.O.?

The diagnosis of *Toxoplasma* encephalitis usually is presumptive because demonstration of cysts or trophozoites in brain tissue is required for a definitive diagnosis. The clinical signs and symptoms of *Toxoplasma* encephalitis can be either focal (indicating a specific region of the brain that is infected or inflamed) or generalized (indicating diffuse inflammation of the brain). *Toxoplasma* encephalitis usually occurs in patients with CD4 counts of <100. Serum titers of antibodies against *T. gondii* typically reflect past infection with the organism and unfortunately do not help delineate whether acute infection is present. In addition, cerebrospinal fluid (CSF) polymerase chain reaction for *Toxoplasma* is not always a reliable diagnostic tool. Most patients with encephalitis have single or multiple ring-enhancing lesions demonstrated on computed tomography scan or MRI of the head. Brain biopsy is reserved for patients with symptoms of encephalitis who are seronegative and for

those who do not respond to presumptive antitoxoplasmosis therapy.[55] Because of the nonspecific diagnosis of *Toxoplasma* encephalitis, a high index of suspicion for other causes of encephalitis (eg, central nervous system [CNS] lymphoma or TB) should be maintained throughout the treatment period for presumed *Toxoplasma* encephalitis. W.O. has overwhelming clinical evidence suggestive of *Toxoplasma* encephalitis. He is HIV positive, has a CD4 count of <100, a positive *Toxoplasma* titer of 1:256 IgG, and a ring-shaped lesion in the brainstem on MRI.

Prophylaxis

Case 77-2, Question 3: Should W.O. have been receiving prophylactic therapy for *T. gondii*?

Similar to many other OIs associated with HIV, therapy for toxoplasmosis can be categorized into primary prophylaxis, treatment of acute disease, and secondary prophylaxis. Primary prophylaxis is currently recommended for PLWH with CD4 counts of <100 who are also IgG-positive for *T. gondii* (see Table 77-1). Many of the agents used to prevent PCP have activity against *T. gondii*: TMP-SMX, dapsone–pyrimethamine–leucovorin, and atovaquone with or without pyrimethamine/leucovorin are effective as primary prophylaxis for *T. gondii.*[12] The increased use of prophylaxis with these agents has significantly decreased the incidence of *Toxoplasma* encephalitis.[2],[12] The double-strength TMP-SMX tablet once daily is recommended as the first-line prophylaxis. Data do not support the use of macrolides or aerosolized pentamidine for *Toxoplasma* prophylaxis. Similarly, data are conflicting regarding the efficacy of pyrimethamine as monotherapy for primary prophylaxis.[56],[57]

Primary prophylaxis may be discontinued in patients who have responded to ART with an increase in the CD4 counts to >200 for >3 months. In addition, data support reinstituting primary prophylaxis when CD4 counts drop <200.

W.O. is currently receiving inhaled pentamidine for PCP prophylaxis. Considering his CD4 count and IgG seropositivity, he should have received primary prophylaxis for *T. gondii.*

Treatment

ACUTE THERAPY

Case 77-2, Question 4: How should W.O.'s presumptive *Toxoplasma* encephalitis be treated?

The first-line treatment of acute *Toxoplasma* encephalitis consists of a combination of sulfadiazine 4 g/day in three or four daily divided doses and pyrimethamine as a single 200-mg loading dose, followed by 50 to 75 mg/day as a single daily dose plus leucovorin 10 to 25 mg PO every day (qd).[12] Induction therapy should be continued for 6 weeks after resolution of symptoms (a treatment course of ~8 weeks) followed by maintenance therapy (secondary prophylaxis). Sulfadiazine toxicity may limit the completion of a full course of therapy in as many as 40% of patients.[58] However, successful desensitization has been documented.[59] W.O.'s clinical and radiologic response should be monitored closely, and other diagnoses should be considered if there is no improvement.

Alternative therapy includes pyrimethamine plus leucovorin with clindamycin 600 to 900 mg IV every 6 hours or 600 mg PO every 6 hours for at least 6 weeks. One controlled trial compared the efficacy and tolerability of pyrimethamine plus sulfadiazine versus pyrimethamine plus clindamycin. Although both regimens were effective, pyrimethamine–sulfadiazine was superior to pyrimethamine–clindamycin. The rate of adverse events was similar with both regimens; however, pyrimethamine–clindamycin led to fewer discontinuations than did pyrimethamine–sulfadiazine (11% vs 30%, respectively).[60] TMP-SMX may be considered a treatment option, particularly in patients who cannot take an oral regimen because the only widely available parenteral sulfonamide is the

sulfamethoxazole component of TMP-SMX. However, there is less in vitro activity and less clinical data to support the use of TMP-SMX as monotherapy for toxoplasmosis.[61] In addition, anticonvulsants should be given to patients with *Toxoplasma* encephalitis and a history of seizures, and corticosteroids may be warranted for focal lesions or edema but should be used cautiously.

Case 77-2, Question 5: W.O. is treated with sulfadiazine–pyrimethamine. What are the limitations to the use of the sulfadiazine component for the treatment of *Toxoplasma* encephalitis?

As with other sulfonamides in PLWH, rashes commonly occur with sulfadiazine therapy.[58] Similar to TMP-SMX, various desensitization regimens have been recommended[34],[59]; however, it may be simpler to use alternative regimens.

Renal function should be monitored throughout therapy. Elevated serum creatinine (SCr) levels, hematuria, or decreased urine output may occur secondary to sulfadiazine-induced crystalluria. The water solubility of sulfadiazine is less than that of other sulfonamides; therefore, hydration (2–3 L/day) is needed to prevent crystalline nephropathy, and aggressive hydration and alkalinization can be used in cases of crystal formation.

Case 77-2, Question 6: What toxicities are associated with the pyrimethamine component?

Pyrimethamine can suppress bone marrow function; thus, concomitant therapy with other medications that suppress marrow function (eg, valganciclovir) may not be tolerated. Leucovorin (10–25 mg/day) is always given in conjunction with pyrimethamine to maintain bone marrow function, although it may not always be successful. Leucovorin doses can be increased to 50 to 100 mg/day in divided doses, if needed, to reverse bone marrow suppression.[12] Folic acid (not folinic acid) should be avoided because it can be used for growth by protozoal organisms, potentially antagonizing

pyrimethamine–sulfadiazine activity.[62] Vitamin preparations containing large quantities of folic acid should be discontinued during therapy for *T. gondii.*

W.O. is not taking any medications that would make him particularly susceptible to the myelosuppressive effects of pyrimethamine, and he is not neutropenic. Consequently, he should be given sulfadiazine and pyrimethamine.

SUPPRESSIVE THERAPY (SECONDARY PROPHYLAXIS)

CASE 77-2, QUESTION 7: Once W.O. has completed acute therapy for his *Toxoplasma* encephalitis, should he receive suppressive therapy?

Most antiprotozoal agents do not eradicate the cyst form of *T. gondii.* Therefore, patients should be administered lifelong suppressive therapy unless immune reconstitution occurs as a consequence of ART.[12] A commonly used regimen for patients who cannot tolerate sulfonamides is pyrimethamine plus clindamycin. However, only the combination of pyrimethamine plus sulfadiazine provides protection against PCP as well. In addition, two small studies of patients receiving maintenance therapy for *Toxoplasma* encephalitis have suggested that sulfadiazine–pyrimethamine is more effective than is clindamycin–pyrimethamine or pyrimethamine alone.[60] The use of atovaquone with or without pyrimethamine is also effective as prophylaxis for both *Toxoplasma* and PCP, but it is significantly more expensive and is only available as a less palatable liquid formulation.

Patients receiving secondary prophylaxis are at low risk for recurrence of *Toxoplasma* encephalitis when they have completed their initial therapy, remain asymptomatic, and have a sustained increase in their CD4 count to >200 after >6 months of ART. Clinicians may obtain a brain MRI as part of the evaluation to determine the end point of therapy. Discontinuation of primary and secondary toxoplasmosis prophylaxis is safe if patients are receiving ART and their CD4 count has increased to >200 for at least 6

months. Secondary prophylaxis should be reintroduced if the CD4 count decreases to <200.[12]

W.O. will be continued on sulfadiazine–pyrimethamine for suppressive therapy for his *Toxoplasma* encephalitis because his CD4 count has decreased to <100. W.O. is currently receiving aerosolized pentamidine for PCP prophylaxis, but because sulfadiazine– pyrimethamine is also protective against PCP, the aerosolized pentamidine can be discontinued. Clindamycin–pyrimethamine is an inferior option because it does not protect against PCP.[12]

ALTERNATIVE THERAPIES

Case 77-2, Question 8: What treatment options exist for patients who cannot tolerate sulfadiazine and do not wish to undergo desensitization?

Clindamycin 600 mg PO every 8 hours plus pyrimethamine and leucovorin at standard doses.[12] Combination therapy with pyrimethamine and leucovorin plus clarithromycin (1 g bid), or atovaquone (750 mg PO four times a day) has shown promise in a limited number of patients.[12]

CYTOMEGALOVIRUS DISEASE

Diagnosis

CASE 77-3

Question 1: P.P.Z. is a 58-year-old male living with AIDS who describes experiencing floating spots, light flashes, and difficulty reading road signs when he drives to his physician. His most recent laboratory results were as follows:

Blood urea nitrogen (BUN), 17 mg/dL
SCr, 0.8 mg/dL
CD4 count, 40 cells/μL

Viral load, 80,000 copies/mL (3 months ago)
WBC count, 1200 cells/L, with 63% polymorphonuclear neutrophil leukocytes

His current weight is 138.89 pounds (63 kg). P.Z.'s medications include a coformulated antiretroviral regimen of tenofovir alafenamide/emtricitabine/bictegravir and dapsone (PCP prophylaxis), although he reports being nonadherent to his medications. He has a history of hematologic intolerance to TMP-SMX. P.Z. is known to have a positive CMV IgG antibody titer. Funduscopic examination reveals alternating areas of hemorrhage and scar tissue (a "cottage cheese and ketchup" appearance) in the proximity of the retina in his left eye.

What is the likely cause of P.Z.'s visual problems?

P.Z. has an inflammation of the retina (retinitis), most likely because of CMV. Many PLWH have been previously infected with CMV, and reactivation typically occurs when CD4 counts are <50. Before ART, the prevalence of CMV disease in patients with AIDS was 30%; however, the incidence of new cases of CMV end-organ disease has declined by 75% to 80% and is estimated to be <6 cases per 100 person-years.[12,63] Although CMV can cause colitis, pneumonitis, esophagitis, hepatitis, and neurologic disease, retinitis is the most common manifestation of active infection in patients with AIDS, accounting for 75% to 85% of CMV end-organ disease. One investigation describing patients with CMV retinitis in the post-ART era found a diverse demographic group with infection; most of them had received ART, and as expected, they had very low CD4 counts.[64] In addition, the characteristics of the disease in this group were similar to those in the pre-ART era. Diagnosis is usually presumptive because biopsy is difficult given the inaccessibility of the retina. Serology is indicative of previous CMV infection, but not an active disease. Cultures (serum, urine, and saliva) may be useful for monitoring therapy, considering that patients frequently have disseminated CMV disease. Patients with positive cultures for CMV while receiving therapy may be at a higher risk for relapse.[65] Typically, the diagnosis of CMV retinitis is based on observations made during a dilated retinal examination and indirect ophthalmoscopy, as was done for P.Z. Lesions appear as fluffy, white retinal patches with retinal hemorrhage.

Once CMV retinitis is diagnosed, the patient should be thoroughly examined for extraocular CMV disease. P.Z. will require regular ophthalmologic examinations, along with retinal photographs, for life. As with HIV therapy, CMV deoxyribonucleic acid (DNA) quantification in plasma or blood cells by polymerase chain reaction may have a role in evaluating treatment efficacy and predicting symptomatic development of CMV disease.[12]

Drug Therapy

Case 77-3, Question 2: What are the treatment options for CMV retinitis, and which one would be preferred for P.Z.?

Several treatment options exist for CMV retinitis: oral valganciclovir, IV ganciclovir, IV ganciclovir followed by oral valganciclovir, IV foscarnet, and IV cidofovir. Alternatives include combined IV ganciclovir plus foscarnet or intraocular injections of ganciclovir, foscarnet, or cidofovir.[12] The efficacy of combined parenteral ganciclovir and foscarnet is similar to that in monotherapy, but it is more toxic. This latter therapy should be reserved for patients with refractory disease.[66]

Intraocular implants (not currently available) and intraocular injections of ganciclovir have similar efficacy in the treatment of CMV retinitis, but their benefit is localized to the infected eye and may lead to an increased risk of contralateral retinitis and extraocular CMV disease. Regimens consisting of systemic anti-CMV therapy have been associated with a 50% reduction in mortality compared with those using intraocular therapy alone.[67] Therefore, concomitant systemic anti-CMV therapy is recommended (eg, oral valganciclovir or IV ganciclovir). The use of ganciclovir intraocular implants with oral valganciclovir has shown to be more effective in preventing relapse of retinitis than is IV ganciclovir and likely oral valganciclovir.[12] Many providers prefer this (or the intraocular injections because the implants are not currently available) as the first-line therapy in patients with immediate sight-threatening lesions,

although others chose oral valganciclovir as the first-line treatment. The choice of agents typically depends on drug efficacy, toxicity, stage of disease, and quality-of-life issues.

GANCICLOVIR

Ganciclovir is an acyclic nucleoside with CMV activity superior to acyclovir. Similar to other nucleosides, ganciclovir must be taken into cells and phosphorylated before it can compete with endogenous nucleotides for binding to viral DNA polymerase. Ganciclovir is poorly absorbed PO (bioavailability, ~5%–9%), and the oral form is no longer marketed. The disposition of ganciclovir is biexponential after IV administration (terminal half-life, ~2.5 hours). The total body clearance is highly dependent on glomerular filtration and tubular secretion.

The dose-limiting toxicity is bone marrow suppression, with neutropenia occurring in ~50% of patients. Thrombocytopenia is also observed. Absolute neutrophil counts (ANCs) and platelets should be monitored weekly during ganciclovir therapy. If the ANC falls to <1000 cells/μL or the platelet count falls to <50,000/μL, the monitoring frequency should be increased to twice weekly.[68] Dosage adjustments must be made in patients with renal dysfunction.

VALGANCICLOVIR

Valganciclovir is an oral monovalyl ester prodrug that is rapidly hydrolyzed to ganciclovir. The absolute bioavailability of ganciclovir from valganciclovir is 60%, and a dose of 900 mg results in ganciclovir blood concentrations similar to those obtained with a dose of 5 mg/kg of IV ganciclovir. Oral valganciclovir and IV ganciclovir are equally effective as induction therapy for newly diagnosed CMV retinitis in patients with AIDS.[69] The frequency and severity of adverse events were similar in the two groups. Based on these data, oral valganciclovir is as effective as and no more toxic than is IV ganciclovir, and the convenience of the oral route suggests it be the drug of choice for the long-term management of CMV retinitis in patients with AIDS.

CIDOFOVIR

Cidofovir is a nucleotide analog that is phosphorylated intracellularly to an active diphosphate metabolite. It is the most potent of all the available anti-CMV compounds and is active against herpes simplex virus (HSV) and VZV, including acyclovir-resistant isolates. Cidofovir does not require viral activation. Because nucleotide analogs do not require virally encoded kinases for their activity, they remain a treatment option for patients who have failed to respond to ganciclovir. Cidofovir is poorly absorbed PO (bioavailability, >5%) and has an intracellular half-life of 17 to 65 hours, resulting in once-weekly induction and every-other-week maintenance therapy.

Eighty percent of this poorly soluble agent is excreted unchanged in the urine via filtration and tubular secretion. Cidofovir is nephrotoxic; however, the administration of probenecid (2 g administered 3 hours before the start of infusion and two 1-g doses administered at 2 and 8 hours after infusion) blocks tubular secretion and reduces nephrotoxicity. Prehydration with 1 L of normal saline is required 1 hour before each dose and, if tolerated, repeated concomitantly with or after the cidofovir infusion. Because nephrotoxicity is the most significant dose-limiting toxicity, other nephrotoxic agents should be discontinued (eg, nonsteroidal anti-inflammatory drugs, and aminoglycosides), and renal function should be carefully monitored throughout therapy (BUN, SCr, and proteinuria). Dosage adjustment must accompany any deterioration in renal function.

The complete blood count (CBC) should be checked at baseline because neutropenia has been reported in ~20% of patients in clinical trials. Hypotony (reduction in intraocular pressure) and uveitis (inflammation of the uveal tract of the eye) have also been reported. Thus, monthly ophthalmologic examinations of the retina are necessary.[12]

The role of cidofovir is limited. Although it offers the advantage of weekly and biweekly dosing, its toxicity greatly limits its utility. Cidofovir appears to be as efficacious as foscarnet and ganciclovir in the treatment of CMV retinitis, but limited comparative studies have

been performed. Finally, the efficacy of cidofovir in the treatment of extraocular CMV (eg, GI disease, pneumonitis, and encephalitis) remains to be established.

FOSCARNET

Foscarnet is a pyrophosphate analog that acts by selectively inhibiting viral DNA polymerases and reverse transcriptase. At doses currently recommended for induction therapy (60 mg/kg every 8 hours or 90 mg/kg IV every 12 hours), peak plasma foscarnet concentrations are higher than those that inhibit CMV in vitro.[70] The dose-limiting toxicity of foscarnet is nephrotoxicity, probably because its poor solubility results in crystallization in nephrons.[68] In one trial, when compared with ganciclovir, patients treated with foscarnet survived ~4 months longer; however, patients treated with foscarnet with reduced creatinine clearance (>1.2 mL/minute/kg) had a poorer survival rate.[71]

Because P.Z. has a low ANC, the bone marrow–suppressive effects of ganciclovir and valganciclovir are of concern. Because he has good renal function (SCr, 0.8 mg/dL), foscarnet or cidofovir would be an option.

Case 77-3, Question 3: P.Z. completes 21 days of foscarnet induction therapy. How can his CMV retinitis be suppressed in future?

The currently available antiviral agents used to treat CMV disease are not curative. After induction therapy, chronic maintenance therapy is indicated for the remainder of P.Z.'s life, unless immune reconstitution occurs as a result of ART. Effective suppressive regimens include valganciclovir, parenteral ganciclovir, parenteral foscarnet, combined parenteral ganciclovir and foscarnet, and parenteral cidofovir. The ganciclovir implant was also effective, but is no longer manufactured. Oral valganciclovir is approved for both acute induction and maintenance therapy, but the published clinical data are limited. In uncontrolled case series, repeated intravitreal injections of ganciclovir, foscarnet, and cidofovir have been shown to

be effective for prophylaxis of CMV retinitis. However, because this therapy is effective only locally and does not protect the contralateral eye or other organ systems, it is usually combined with oral valganciclovir.

Guidelines suggest that discontinuation of prophylaxis may be considered in patients with CMV retinitis who are taking ART with a sustained (>3–6 months) increase in the CD4 count to >100 and have remained disease free for >30 weeks. The decision to discontinue suppression should be done in consultation with an ophthalmologist and be based on the magnitude and duration of the CD4 increase and viral load suppression, the anatomic location of the retinal lesions, and the degree of vision loss.[12] All patients who have had anti-CMV maintenance therapy discontinued should continue to undergo regular ophthalmologic monitoring for early detection of CMV relapse and for immune reconstitution uveitis.

Relapse or Refractory Cytomegalovirus Retinitis

Case 77-3, Question 4: After 5 months of maintenance therapy with foscarnet, a routine funduscopic examination reveals retinal CMV disease progression. How should P.Z.'s retinitis be managed at this time?

Most patients with CMV not receiving ART while undergoing maintenance treatment eventually relapse.[12] For the first relapse, repeat induction therapy followed by maintenance therapy with the same drug is beneficial in most patients. Because P.Z. has tolerated foscarnet therapy thus far, he should receive another course of induction therapy. After reinduction, P.Z. should receive a higher maintenance dosage (120 mg/kg/day).[12]

It is important to distinguish between relapse and refractory disease. Relapse, as in the case of P.Z., is defined as the recurrence of clinically apparent viral activity and is usually caused by a decline in immune function, insufficient delivery of drug into the eye, or resistant CMV strains. Relapse can effectively be managed by repeat induction therapy of the same drug. If the relapse is caused

by a resistant virus, the patient may benefit from a change in therapy. Ganciclovir-resistant CMV strains occur by two mechanisms. DNA polymerase mutation at the *UL54* gene is observed in ~20% of ganciclovir-resistant strains. This mutation usually confers resistance to cidofovir and, to a lesser extent, foscarnet.[12] Most ganciclovir-resistant CMV strains have *UL97* mutations. *UL97* mutations are incapable of monophosphorylating ganciclovir. Cidofovir and foscarnet are appropriate alternatives to treat strains with *UL97* mutations. Patients who receive extensive ganciclovir treatment (>6–9 months) may present with highly ganciclovir-resistant strains containing *UL54* and *UL97* mutations.[72] Cidofovir may be considered in most patients who relapse while receiving ganciclovir or foscarnet. Although ganciclovir-resistant and foscarnet-resistant strains of CMV have been reported, their precise role in the clinical failure of these regimens is not known. Because of the different mechanisms of action of ganciclovir and foscarnet, strains resistant to one drug may retain sensitivity to the other.[73] Resistant or relapsing CMV retinitis may be treated by the administration of local ocular therapy via intravitreal injection of ganciclovir or foscarnet (see the section on Local Treatment).

Refractory CMV retinitis is defined by disease progression because of ineffective therapy. This phenomenon is observed in two clinical situations: when the disease persists with minimal or no response during induction therapy and when long-term control is inadequate with maintenance therapy. Refractory CMV disease has been defined in clinical trials as two relapses occurring within 10 weeks despite repeat induction and maintenance therapy. Treatment options for refractory CMV retinitis include reinduction with ganciclovir at higher dosages (7.5 mg/kg/dose every 12 hours, followed by maintenance doses of 10 mg/kg/day) or reinduction using combination therapy (IV ganciclovir plus foscarnet).[12] Refractory CMV retinitis can be treated with local ocular therapy via intravitreal injection of ganciclovir or foscarnet.[12]

Local Treatment

Case 77-3, Question 5: What is the role of intravitreal injections in CMV retinitis?

INTRAVITREAL INJECTIONS

Intravitreal administration of ganciclovir or foscarnet through a small-gauge needle is a method of selectively delivering the drug to the site of infection. Ganciclovir and foscarnet doses of 0.2 to 2 mg and 1.2 to 2 mg, respectively, are administered two or three times per week for active disease, followed by weekly maintenance injections.[12] Potential complications of intravitreal injections include bacterial endophthalmitis, vitreous hemorrhage, and retinal detachment. Importantly, in contrast to systemic therapy, local instillation of a drug is associated with a higher risk of CMV disease developing in the contralateral eye as well as extraocular sites.

CRYPTOCOCCOSIS

Clinical Presentation and Prognosis

CASE 77-4

Question 1: A.S. is a 28-year-old female with congenital HIV. She weighs 105.82 pounds (48 kg). She presents with a fever (103 °F [39.44 °C]) and a 2-week history of "splitting headaches." Laboratory test results include the following:

Hemoglobin, 11.2 g/dL
WBC count, 4100 cells/μL
Platelets, 73,000/L
SCr, 0.9 mg/dL
Glucose, 94 mg/dL
CD4 count, 47 cells/μL

A.S. has been out of care for more than a year; the last time she was seen in clinic, she was prescribed a single-tablet regimen consisting of darunavir/cobicistat/tenofovir alafenamide/emtricitabine. Physical examination

reveals no nuchal rigidity. With the exception of moderate lethargy, her neurologic examination is unremarkable. Her chest radiograph and three sets of blood culture results for bacteria and fungi are negative. A computed tomography scan is nondiagnostic. Lumbar puncture reveals the following CSF findings:

Glucose, 45 mg/dL
Protein, 90 mg/dL
WBC count, 10 cells/μL
Cryptococcal antigen titer, 1:2048 IU
Intracranial pressure (ICP), 24 cm H_2O (normal, 8–22 cm H_2O)

How is A.S.'s clinical presentation typical of a patient with AIDS and cryptococcal meningitis? What is her likely prognosis?

In the pre-ART era, cryptococcosis developed in ~6% to 10% of patients with AIDS in the United States, with meningitis being the most common clinical presentation.[74] In the era of ART and azole prophylaxis, a significant decline in the incidence of cryptococcosis has been observed.[74] The initial portal of entry is the lungs, where the organism is normally contained by an intact immune system. Cryptococcal disease typically develops in patients with profound defects in cell-mediated immunity (ie, CD4 counts, <50). Unlike bacterial meningitis, cryptococcal CNS infection has a much more insidious onset; the most common symptoms are fever and headache. Less frequent signs and symptoms include nausea and vomiting, meningismus, photophobia, and altered mental status. Focal neurologic deficits and seizures are observed in <10% of patients. CSF glucose is decreased, whereas CSF proteins are usually elevated. CSF cryptococcal antigen titer and CSF culture results are frequently positive. These findings, along with the clinical presentation, form the basis for the diagnosis. The overall outcome is poor, with a mean survival of 5 months in patients not receiving ART. Relapse within 6 months occurs in 50% of patients who do not receive suppressive therapy. Altered mental status at baseline, CSF WBC count of <20 cells/μL, high CSF cryptococcal antigen titer (>1:1,000), and an elevated initial CSF opening pressure of >20 cm H_2O have all been associated with a poor prognosis.[74]

A.S.'s CD4 count is 47. She has a temperature of 103 °F (39.44 °C) and has experienced "splitting headaches" for about a week. Her clinical presentation is typical of cryptococcal meningitis in patients living with AIDS. The CSF WBC count of 10 cells/μL, high cryptococcal antigen titer, and ICP >20 cm H_2O suggest a poor prognosis.[75] If left untreated, cryptococcal meningitis is fatal.

Treatment

AMPHOTERICIN B

Case 77-4, Question 2: How should A.S.'s acute cryptococcal meningitis be managed?

The current treatment recommended for cryptococcal meningitis is liposomal amphotericin B, 3 to 4 mg/kg/day IV, plus flucytosine (100 mg/kg/day) given PO in four divided doses as induction therapy for 14 days. Once the patient is stable (eg, afebrile, with the resolution of symptoms), then consolidation therapy with oral fluconazole 400 mg/day for 8 weeks or until CSF cultures are sterile can be initiated. After consolidation therapy, daily suppressive therapy with fluconazole 200 mg should be continued indefinitely unless immune reconstitution occurs with ART. Owing to lower rates of nephrotoxicity and infusion-related reactions, lipid-based amphotericin B, specifically liposomal amphotericin B, has supplanted amphotericin B deoxycholate as the agent of choice.[76,77]

Although the aforementioned regimen is highly effective, the ability to rapidly reduce A.S.'s ICP will also significantly improve her clinical course. Removal of 10 to 20 mL of spinal fluid by repeat lumbar puncture is recommended for patients with an ICP >20 cm H_2O (A.S.'s ICP is 24 cm H_2O). An additional intervention to consider reducing A.S.'s elevated ICP is the insertion of an intraventricular shunt.[12]

CASE 77-4, QUESTION 3: What is the evidence for adding flucytosine to amphotericin B in the acute treatment of A.S.? What are the disadvantages of this combination?

Amphotericin B binds to sterols in the fungal cell membrane, resulting in leakage of cytoplasmic contents. Flucytosine is an antimetabolite type of antifungal drug that is activated by deamination within the fungal cells to 5-fluorouracil. It inhibits fungal protein synthesis by replacing uracil with 5-fluorouracil in fungal RNA, and it also inhibits thymidylate synthase via 5-fluorodeoxy-uridine monophosphate, interfering with fungal DNA synthesis. Flucytosine, a purine analog, is ~10% converted to 5-fluorouracil, an antimetabolite, which is the mechanism for its potential bone marrow toxicity.

A classic prospective study conducted in patients who are HIV negative favored the use of the combination.[78] The protocol randomly assigned patients to receive either amphotericin B monotherapy (0.4 mg/kg/day IV for 6 weeks followed by 0.8 mg/kg/day IV every other day for 4 weeks) or amphotericin B plus flucytosine (150 mg/kg/day PO divided every 6 hours) for 6 weeks. Fewer failures or relapses, more rapid CSF sterilization, and less nephrotoxicity occurred in the combination group, although overall mortality was not different. However, approximately one-fourth of the patients in the combination arm developed leukopenia, thrombocytopenia, or both.

If flucytosine is chosen as adjunctive therapy, renal function and CBCs should be monitored closely for these adverse effects. A.S. is at increased risk for granulocytopenia because of her HIV infection.

The comparative trial forming the basis for the current recommendations for the treatment of acute cryptococcal meningitis in PLWH evaluated a higher dose of IV amphotericin B (0.7 mg/kg/day) with or without flucytosine given at a lower dose (25 mg/kg/dose PO every 6 hours) for 2 weeks.[75] The study evaluated 381 patients with an acute first episode of cryptococcal meningitis. The second part of this trial randomly reassigned patients who were

stable or had improved to either a fluconazole or an itraconazole treatment arm for an additional 8 weeks as consolidation therapy. Sixty percent and 51% of patients receiving amphotericin B plus flucytosine, and amphotericin B alone, respectively, had sterile CSF culture findings at 2 weeks of therapy. No significant differences were noted between groups in the percentage of patients who had negative culture results at 2 weeks. Importantly, the addition of flucytosine to amphotericin B was not associated with a significant increase in drug toxicities at 2 weeks. Fluconazole and itraconazole were similar in efficacy. However, multivariate analysis revealed two factors that were independently associated with a higher rate of CSF sterilization: the addition of flucytosine and the randomization to fluconazole. A more recent trial randomized 299 patients to amphotericin B (1 mg/kg/day) for 4 weeks, amphotericin B (1 mg/kg/day) plus flucytosine (100 mg/kg/day divided) for 2 weeks, or amphotericin B (1 mg/kg/day) plus fluconazole (400 mg bid) for 2 weeks. Patients receiving amphotericin B and flucytosine had lower mortality rates and significantly increased rates of yeast clearance from CSF. Rates of adverse events were similar between groups, with the exception of more frequent neutropenia in patients receiving a combination therapy. The addition of fluconazole provided no survival benefit.[79]

FLUCONAZOLE

CASE 77-4, QUESTION 4: Could A.S. be treated with fluconazole instead of amphotericin B for acute cryptococcal meningitis?

Fluconazole, one of the triazole antifungal agents, inhibits a fungal cytochrome P-450 (CYP) enzyme necessary for the conversion of lanosterol to ergosterol. Without ergosterol, the fungal cell membrane becomes defective and loses its selective permeability properties. Unlike itraconazole, fluconazole is well absorbed PO even in the presence of an elevated gastric pH. Fluconazole has excellent CNS penetration and a good safety profile, but it is likely a

secondary choice in the initial treatment of cryptococcal meningitis. In a prospective, randomized, multicenter trial, the National Institute of Allergy and Infectious Diseases Mycoses Study Group and the AIDS Clinical Trial Group compared amphotericin B with 200 mg/day of oral fluconazole (after a 400-mg loading dose) for 10 weeks in 194 patients.[80] The dose of amphotericin B (mean dose, 0.4–0.5 mg/kg/day) and the possible addition of flucytosine were left to the discretion of the individual investigators. Although the overall mortality was similar (14% for amphotericin B vs 18% for fluconazole), more patients treated with fluconazole died during the first 2 weeks of treatment (15% vs 8%; $P = 0.25$). Furthermore, the median time to the first negative CSF culture finding in the successfully treated patients was shorter in the amphotericin B group compared with fluconazole (16 vs 30 days). In a small, prospective, randomized trial of 20 male patients with AIDS, oral fluconazole (400 mg/day) for 10 weeks was compared with IV amphotericin B (0.7 mg/kg/day for 1 week, followed by the same dose three times weekly for 9 weeks) combined with flucytosine (150 mg/kg/day).[81] There were four deaths in the fluconazole group and none in the amphotericin B group ($P = 0.27$). Eight of the 14 patients in the fluconazole group failed to respond to treatment, whereas none in the amphotericin B group failed to respond. The mean duration of positive CSF cultures was 41 days in the fluconazole group and 16 days in the amphotericin B group ($P = 0.02$). These results, taken together, have led most clinicians to choose amphotericin, with or without flucytosine, as initial treatment for severe cryptococcal meningitis. Although increased doses of fluconazole have been proposed, it is unknown whether these will result in improved outcomes. High doses of fluconazole are being investigated further for patients in the developing world where the use of IV amphotericin may not always be feasible. Considering the severity of her meningitis, A.S. should be treated acutely with liposomal amphotericin B and not with fluconazole.

DURATION OF THERAPY

CASE 77-4, QUESTION 5: How long should treatment continue for A.S.'s cryptococcal meningitis?

Once A.S. completes 2 weeks of acute induction therapy with liposomal amphotericin B and flucytosine, she should be switched, if stable, to oral fluconazole 400 mg/day for consolidation therapy. Consolidation should be continued for an additional 8 to 10 weeks, followed by lifelong suppressive therapy with fluconazole 200 mg/day[75] (see the section on Maintenance Therapy).

MAINTENANCE THERAPY

CASE 77-4, QUESTION 6: Should A.S. receive maintenance therapy after successful treatment?

After induction and consolidation treatment of cryptococcal meningitis, A.S. and all patients with AIDS should receive maintenance therapy indefinitely, unless immune reconstitution occurs as a result of ART.[12],[74],[75] A higher relapse rate and a shorter life expectancy have been observed in patients who did not receive chronic secondary prophylaxis.[82] Fluconazole (200 mg once daily) has emerged as the suppressive treatment of choice. In a randomized, placebo-controlled trial of 61 patients with AIDS, four recurrent cases of meningitis developed in the placebo group and none in the fluconazole group.[83] A multicenter, comparative trial randomized patients to receive either weekly amphotericin B 1 mg/kg/day IV or 200 mg/day of fluconazole PO.[84] Of 189 patients enrolled, 18% of the patients in the amphotericin B group relapsed, compared with 2% in the fluconazole group. Serious toxicities were more frequent in the amphotericin B group.[75] The newer triazole antifungals, posaconazole and voriconazole, have limited experience as primary or maintenance therapy for patients with cryptococcosis and are associated with many drug interactions with ART.[12]

According to the OI guidelines,[12] adult and adolescent patients are at a low risk for recurrence of cryptococcosis when they have

completed a course of initial therapy, remain asymptomatic, and have a sustained increase (eg, >6 months) in their CD4 counts to at least 200 after ART. Thus, discontinuing chronic maintenance therapy among such patients is reasonable. Recurrences may occur, and some specialists recommend a repeat lumbar puncture to determine whether the CSF culture result is negative before stopping therapy. Maintenance therapy should be reinitiated if the CD4 count decreases to <200.

Primary Prophylaxis

Case 77-4, Question 7: What is the role of primary prophylaxis in cryptococcal meningitis?

Primary prophylaxis against cryptococcal disease in PLWH has been studied in a few clinical trials.[85],[86] In an open-label study, fluconazole (100 mg/day) was administered to all patients (329 PLWH) with CD4 counts <68. These results were compared with 337 historical controls from the pre-ART era.[85] Sixteen cases of cryptococcal meningitis occurred in the historical controls (4.8%) compared with only one case in the fluconazole group (0.3%). In a prospective, randomized AIDS Clinical Trial Group study, fluconazole 200 mg/day was compared with clotrimazole troches (10 mg five times a day) for the prevention of fungal infections in 428 patients with advanced HIV disease. After a median follow-up of 35 months, 32 cases of invasive fungal infection were confirmed. Of these, the majority (17 of 32) were cryptococcosis: 2 cases in the fluconazole group and 15 cases in the clotrimazole group. The greatest benefit derived from fluconazole was observed in patients with CD4 counts of <50.[86] However, no effect on survival was noted. A randomized, double-blind, placebo-controlled trial of fluconazole 200 mg three times weekly versus placebo in Ugandan adults with CD4 counts <200 found fluconazole prophylaxis to be effective prophylaxis against cryptococcal disease, with 18 patients in the placebo group developing cryptococcal disease versus one patient in the

fluconazole group. There was no difference in all-cause mortality between the groups.[85]

Fluconazole resistance has been reported in PLWH receiving a long-term therapy.[87] In addition to the potential for resistance, other concerns include the lack of survival benefits associated with prophylaxis, the possibility of drug interactions, and cost. In light of these concerns, the guidelines currently do not recommend primary prophylaxis for this disease (see Table 77-1).[12]

MYCOBACTERIUM TUBERCULOSIS

Clinical Presentation

CASE 77-5

QUESTION 1: C.J., a 45-year-old male prison inmate with AIDS, presents with fever, cough, and occasional night sweats. A tuberculin purified protein derivative (PPD) skin test result is negative. Two acid-fast bacilli (AFB) sputum smears also return negative results. Chest radiograph reveals hilar adenopathy with a questionable right middle lobe localized infiltrate. No cavitary lesions are seen. His antiretroviral medications include abacavir, lamivudine, and dolutegravir. Three months ago, his CD4 count was 120 cells/μL, and his viral load was 5200 copies/mL.

Why is infection with *Mycobacterium tuberculosis* a strong possibility in C.J.?

TB is the third leading cause of mortality attributed to infection worldwide, with nearly 2 million deaths in 2016.[88] Low- to middle-income countries account for 95% of deaths from *M.* tuberculosis. In the United States, 8916 cases of TB occurred in 2019, which is the lowest number of TB cases on record.[89] The recognized link between HIV and TB, along with an increase in clinical and public health resources, has subsequently resulted in a decline in the incidence of TB in the United States.[89]

C.J. presents with fever, cough, night sweats, and a right middle lobe infiltrate with hilar adenopathy, consistent with TB. Furthermore,

his HIV status in combination with his incarceration increases the probability of *M. tuberculosis* infection, including multidrug-resistant isolates. C.J. will be started with the standard four-drug regimen: isoniazid, rifampin (or rifabutin), pyrazinamide, and ethambutol.[12] (See Chapter 68, Tuberculosis, for a more comprehensive approach to TB treatment.)

Case 77-5, Question 2: Why are the negative tuberculin skin test result, negative sputum smear findings for AFB, and lack of cavitary lesions in C.J. still consistent with *M. tuberculosis* infection?

PLWH with CD4 counts <200 commonly present with extrapulmonary TB, along with or in the absence of pulmonary disease. These extrapulmonary sites include lymph nodes, bone marrow, spleen, liver, CSF, and blood.[12] The chest radiograph in PLWH may reveal hilar or mediastinal adenopathy or localized infiltrates in the middle or lower lung fields.

In PLWH, it is unusual to see typical apical infiltrates or cavitations. Furthermore, concomitant PCP may confuse the interpretation of chest radiographs. Finally, anergy (a state of immune unresponsiveness) is common in HIV disease. Thus, definitive diagnosis of TB rests on positive culture findings from sputum or other tissue and body fluid specimens.[12] Unlike many other AIDS-related OIs, CD4 count is not a reliable predictor of an increased risk for TB diseases, and patients can have relatively high CD4 counts at the time of TB development.

PLWH: DRUG-SUSCEPTIBLE TUBERCULOSIS

CASE 77-6

Question 1: K.D., a 26-year-old male living with HIV, comes in for a routine clinic visit. It is discovered that he is a household contact of a person known to have active, untreated, drug-susceptible TB. His CD4 count is 350 cells/μL. A tuberculin skin test (five tuberculin units of PPD) is administered, and he is instructed to return to the clinic in 48 hours. His PPD has returned negative

findings in the past, and he has demonstrated delayed hypersensitivity responsiveness.

How should the results of K.D.'s skin tests be interpreted, and should he be treated for latent TB considering his known exposure to TB?

Current guidelines recommend 9 months of isoniazid prophylaxis (300 mg/day PO) plus pyridoxine (50 mg/day PO) for all PLWH who have at least a 5-mm induration reaction to PPD and no evidence of active TB (negative chest radiograph and no clinical symptoms), unless otherwise contraindicated and regardless of Bacillus Calmette–Guerin vaccination status.[12] Alternatively, patients can receive rifapentine plus isoniazid plus pyridoxine once weekly for 12 weeks. The administration of Bacillus Calmette–Guerin vaccine to PLWH is contraindicated because of the potential to cause disseminated disease.[12] A >5-mm reaction in PLWH is considered positive.[12] Few isoniazid prophylaxis failures have been reported, although this finding has not been systematically studied. Persons who cannot take isoniazid or who have been exposed to a known isoniazid-resistant strain should use either rifampin or rifabutin alone for 4 months as alternatives, being mindful of potential drug interactions with ART.[12] All PLWH, irrespective of age, PPD results, or prior course of chemoprophylaxis, should be given chemoprophylaxis if they are in close contact with persons who have active TB. Prophylaxis also should be given for anergic, PLWH who have been in contact with patients known to have active TB.[12] Before the treatment of latent TB is begun, active TB needs to be ruled out. K.D. should undergo chest radiography and clinical evaluation to rule out active disease. The CDC no longer recommends routine anergy testing in these patients.[12]

PLWH: PROTEASE INHIBITORS, NONNUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS, CCR5 ANTAGONISTS, AND INTEGRASE INHIBITORS

CASE 77-7

Question 1: F.C., a 36-year-old female living with HIV, diagnosed 6 months ago, was found to have active TB (pulmonary infiltrates on chest radiographs, sputum AFB stain and positive culture finding, and culture pansensitive). She is taking tenofovir alafenamide, emtricitabine, darunavir, cobicistat, and fluconazole, and her CD4 count is 300 cells/μL.

What factors must be considered when selecting TB therapy for F.C.?

The use of protease inhibitors in the treatment of PLWH coinfected with TB increases the potential for drug interactions with rifamycin derivatives (rifampin and rifabutin). Because the rifamycins are potent inducers of the hepatic CYP system (eg, CYP3A4), they can induce metabolism of the protease inhibitors, resulting in subtherapeutic levels. Conversely, the protease inhibitors elevate rifamycin serum levels by inhibiting their metabolism and increasing toxicities, such as rifabutin-associated uveitis (inflammation of the uveal tract of the eye; see Chapter 68, Tuberculosis).

According to recent guidelines, rifampin should not be coadministered with any standard protease inhibitors (boosted or not with ritonavir or cobicistat), etravirine, nevirapine, rilpivirine, or elvitegravir.[11,88] Dolutegravir should be dosed 50 mg bid if combined with rifampin.[11] Rifabutin should be given at 50% of the usual dose (ie, reduced from 300 to 150 mg/day or 300 mg three times a week) with ritonavir- or cobicistat-boosted protease inhibitors.[11] Rifabutin can be used in full doses with nevirapine, etravirine, and rilpivirine; however, the rilpivirine dose should be increased to 50 mg daily.[90] If etravirine is coadministered with a ritonavir-boosted protease inhibitor, rifabutin should not be coadministered.[11] Tenofovir/emtricitabine/elvitegravir/cobicistat should not be coadministered with rifabutin; however, no dose adjustment is needed when combined with dolutegravir or raltegravir.[11] Sequential treatment of TB followed by HIV treatment is not recommended.[12] Three clinical trials have demonstrated a reduction in mortality and HIV-related diseases when antiretrovirals are given during TB treatment.[91–93]

If a change in her ART regimen is not possible, a reduced dose of rifabutin (150 mg daily or 300 mg three times per week) is

recommended when coadministered with darunavir/cobicistat. She will receive isoniazid, rifabutin, pyrazinamide, and ethambutol daily for 8 weeks followed by isoniazid and rifabutin daily or three times weekly for 6 months.

MYCOBACTERIUM AVIUM COMPLEX DISEASE

Clinical Presentation

CASE 77-8

QUESTION 1: M.E., a 38-year-old female living with HIV who has a history of IV drug use, presents with fevers, drenching night sweats, a poor appetite, and a 20-pound (9.07-kg) weight loss (>15% of baseline) during the past 4 months. M.E. has been off all ART for the past year because of drug intolerance. She has a past medical history of recurrent herpes zoster, PCP, and cryptococcal meningitis. Her current medications include one TMP-SMX double-strength tablet once daily and an occasional valacyclovir dose when she feels the herpes zoster "is beginning to start"; she is not on MAC prophylaxis therapy. Physical examination reveals a cachectic female with mild hepatosplenomegaly. Pertinent laboratory test results include the following:

Hematocrit, 23%
WBC count, 3500 cells/L, with 68% neutrophils, 2% bands, 22% lymphocytes, and 8% monocytes
Absolute CD4 count, 25 cells/μL
Viral load, 400,000 copies/mL
Aspartate transferase, 135 IU/L
Alanine aminotransferase, 95 IU/L
Alkaline phosphatase, 186 IU/L

The chest radiograph is unremarkable. Based on these findings, a presumptive diagnosis of MAC infection is made.

Why is M.E.'s clinical presentation consistent with MAC infection?

Disseminated MAC infection is common in patients with end-stage AIDS. On autopsy, MAC organisms are observed in the lungs and multiple other bodily tissues.[94] The predominant organism in PLWH

is *M. avium* (>95% of typeable isolates).[12] The risk of developing disseminated MAC infection is highest in patients with a CD4 count <50.[12] Poor prognostic indicators include prior OI, high plasma HIV RNA levels, previous colonization of the respiratory or GI tract with MAC, and reduced in vitro lymphoproliferative immune responses to *M. avium* antigens.[12]

M. avium is a ubiquitous organism found in food, water, soil, and house dust. The most likely portal of entry is either the GI or respiratory tract. Common presenting symptoms associated with MAC infection include fever, night sweats, anorexia, malaise, profound weight loss (>10% body weight), anemia, lymphadenopathy, and diarrhea.[12] M.E.'s fevers, drenching night sweats, poor appetite, 20-pound (9.07-kg) weight loss, and mild hepatosplenomegaly are consistent with MAC infection. In particular, her CD4 count of 25 puts her at risk for this OI.

Treatment

INITIATION

Case 77-8, Question 2: Why is it appropriate to initiate M.E.'s drug therapy before blood culture results have documented the presence of MAC?

Disseminated MAC is best diagnosed by peripheral blood cultures. However, initial testing often includes AFB on a blood smear.[12] Conventional culture methods using solid media may have a turnaround time of as long as 8 weeks; however, radiometric broth systems signaling the release of carbon 15-labeled CO_2 from mycobacteria may detect bacterial growth in 7 to 10 days.[95] Identification of the organism (*M. tuberculosis* vs atypical mycobacteria) by conventional biochemical methods may take weeks to months. Techniques using DNA probes make diagnosis possible within several hours.[95] Quantitative blood cultures have been useful to monitor the effects of drug therapy, but may not be

practical on a routine clinical basis. Radiometric broth methods also may provide in vitro drug susceptibility in another 7 to 10 days. Even with the availability of all these laboratory tests, results generally are not available for 2 to 3 weeks. In view of this lag time, empiric therapy should be initiated as quickly as possible. Although MAC is typically isolated from blood, the organism can also be demonstrated via acid-fast smears of lymph node, liver, or bone marrow biopsies. Because these organs are rich in monocytes (the target cells for MAC infection), the organism load may be high (up to 10^{11} colony-forming units/mL).

DRUG SUSCEPTIBILITY AS A BASIS FOR TREATMENT

CASE 77-8, QUESTION 3: Should M.E.'s therapy be based on in vitro drug susceptibility results?

Correlation between in vitro drug susceptibility results and clinical efficacy has not been clearly established for MAC.[95],[96] In addition, drug susceptibility studies also may not correlate with clinical efficacy because in vitro results for individually tested drugs may show resistance, but combination therapy may be additive or synergistic. Finally, some antimycobacterial agents exhibit large differences between the minimum inhibitory concentration and maximum bactericidal concentration. This finding may reflect the difficulty in eradicating this organism, particularly in a severely immunocompromised host. Despite these limitations, in vitro drug susceptibility testing is only recommended for macrolide antibiotics because of the correlation with clinical outcomes.[97]

DRUG THERAPY

CASE 77-8, QUESTION 4: What drug regimens could be selected to treat M.E.?

The guidelines recommend a two-drug or more MAC regimen because monotherapy can lead to breakthrough bacteremia and

resistance; at least one of these drugs must be a macrolide. Clarithromycin (500 mg PO bid) is the preferred agent because there are more clinical data; however, if intolerable or significant drug interactions need to be avoided, azithromycin 500 to 600 mg PO qd is an alternative. Doses of clarithromycin >1 g/day in the treatment of MAC have been associated with increased mortality.[12] Ethambutol (15 mg/kg/day PO) is recommended as the second agent. Several drugs can be used as the third agent, including rifabutin (300 mg/day), amikacin (10–15 mg/kg/day), and fluoroquinolones. The choice of the third agent depends on the severity of the illness, including high mycobacterial loads, CD4 count <50, drug interactions, hepatic and renal function, patient tolerability, patient compliance, and cost. Long-term therapy may be discontinued in patients who have completed a course of >12 months of treatment for MAC, remain asymptomatic, and have a sustained increase (eg, >6 months) in their CD4 count to >100 after ART.[12]

Although four-drug regimens have been used, one study observed that a three-drug macrolide regimen (clarithromycin, ethambutol, and rifabutin) was more effective than was a four-drug regimen (ciprofloxacin, clofazimine, ethambutol, and rifampin).[98] Benefits of the macrolide regimen included more rapid clearing of MAC bacteremia and a longer duration of survival. Rifabutin, at 600 mg/day, induced uveitis in approximately one-third of patients. Subsequently, the rifabutin dosage was lowered to 300 mg/day, and the incidence of uveitis decreased to 5.6%. Although clearance of bacteremia was superior at the higher rifabutin dose, no differences in survival were observed.

IRIS can also occur with MAC disease. IRIS-associated fever and lymphadenitis are difficult to differentiate from active MAC disease. IRIS most commonly occurs in patients with MAC and very low CD4 counts with the initiation of ART. The disease is often self-limiting and requires no therapy; however, steroid therapy may be warranted in severe disease. For this reason, for patients not taking ART, it may be warranted to administer MAC therapy for 2 weeks before the initiation of ART to minimize the risk of IRIS.[12]

M.E. is placed on a regimen of azithromycin 600 mg daily and ethambutol 15 mg/kg/day. Considerations for the addition of a third-line agent include the severity of the illness, potential drug interactions, tolerability, hepatic and renal function, and cost. M.E. must be counseled regarding the slow response to treatment. If she improves, therapy should be continued, and ART should be reinstituted.

Monitoring therapy

CASE 77-8, QUESTION 5: How should M.E. be monitored?

The primary goals of MAC therapy are to eradicate or reduce the number of ***M. avium*** organisms, decrease symptoms, enhance quality of life, and prolong survival. M.E. should be monitored for symptomatic relief (temperature spikes and frequency of night sweats), as well as for a microbiologic response (colony-forming units/mL). Clinical response, as well as a decline in the quantity of mycobacteria, is expected in 2 to 4 weeks but may be delayed in patients with extensive disease. If no clinical response is seen in 4 to 8 weeks, repeat blood cultures for MAC should be obtained along with repeat susceptibility testing for clarithromycin and azithromycin. If resistance is observed or suspected, two new drugs should be added based on susceptibility testing with or without the macrolide. If the organism is found to be susceptible to macrolides, therapy should be continued and adherence, absorption, tolerance, and drug interactions should be considered.[12] If the problem is determined to be drug absorption, IV agents can be considered. M.E. should also be followed up for the development of toxicities related to drug therapy. Furthermore, because many drugs used to treat MAC infections are associated with drug interactions, this issue must be considered each time a new drug is prescribed. In some cases, drug doses need to be modified or alternative drugs should be selected to prevent adverse events or therapeutic failures.[12,97]

Case 77-8, Question 6: What drug(s) should be used to provide primary prophylaxis against MAC infection?

Prophylaxis

MAC prophylaxis is not recommended for patients who are initiated on ART and is only recommended for those who are not on fully suppressive ART after active disseminated MAC has been ruled out.[12] Options include clarithromycin (500 mg bid) or azithromycin 1200 mg every week or 600 mg twice weekly for persons with a CD4 count <50. Although the combination of azithromycin and rifabutin is more effective than is azithromycin alone, the increased cost, adverse events, potential for drug interactions with rifabutin, and the absence of a survival benefit preclude this regimen from being routinely recommended. If neither clarithromycin nor azithromycin is tolerated, rifabutin 300 mg/day may be used (Table 77-1).[12]

The decision to use clarithromycin or azithromycin (both first-line recommendations for primary prophylaxis) is based on patient compliance and the potential for drug interactions. Azithromycin (1200 mg once weekly or 600 mg twice weekly) may be preferable for a patient who has difficulty with adherence. In contrast to clarithromycin, azithromycin does not affect the CYP enzyme system and is therefore less likely to interact with other drugs. M.E. would have benefited from MAC prophylaxis when her CD4 count decreased to <50 because she was not on ART.

MAC prophylaxis can be discontinued when they initiate effective ART and would be reinitiated if CD4 <50 only if not on suppressive ART.[12]

MUCOCUTANEOUS CANDIDIASIS

CASE 77-9

Question 1: P.J. is a 45-year-old male living with HIV who was started on dolutegravir and tenofovir alafenamide/emtricitabine when he was diagnosed 1 year ago. P.J. has not been seen in the clinic since his initial presentation. He appears today with difficult, painful swallowing and diffuse pain. On examination, localized white plaques are observed in the oral cavity. His CD4 count is 280 cells/μL.

What is the most likely cause of this patient's dysphagia and odynophagia?

Candida can cause both oropharyngitis and esophagitis in PLWH typically when CD4 counts are >200 cells/μL. In addition, patients can present with CMV, HSV, or aphthous ulcers in the oropharynx. Symptoms include dysphagia, odynophagia, and thrush (with *Candida* infections). Oral ulcers are common with HSV, rare with *Candida*, and uncommon with CMV or aphthous ulcers. Pain is usually diffuse in *Candida* infections and more focused with HSV, CMV, and aphthous ulcers. Fever is primarily associated with CMV.[12]

Most infections are caused by *Candida albicans*; however, because of the exposure of fluconazole, emergence of non-*albicans* species such as *C. glabrata* has been seen, and in some cases led to refractory candidiasis.[12] Patients with localized white plaques in the oral cavity likely have oral candidiasis (thrush), and should be started on antifungal therapy. Oral fluconazole (100 mg once daily) is considered the drug of choice for the treatment of oropharyngeal candidiasis because it is more convenient and better tolerated than are topical therapies. Patients may also be treated with local antifungal therapy (eg, "swish and swallow" nystatin suspension, 1 tsp four or five times daily, or clotrimazole troches four or five times daily). The preferred therapy for esophageal candidiasis is 14 to 21 days of fluconazole at higher doses (up to 400 mg PO or IV daily). Alternative therapies include itraconazole and posaconazole (for oropharyngeal disease) and voriconazole, isavuconazole, anidulafungin, caspofungin, micafungin, and amphotericin B (for esophageal disease).[12] Primary prophylaxis is not recommended for candidiasis.[12]

A presumptive diagnosis of *Candida* esophagitis can be made for P.J. because he presents with oral pharyngeal candidiasis,

dysphagia, and odynophagia. P.J. should be empirically treated with fluconazole 200 mg/day for 14 to 21 days. If he is unresponsive to fluconazole, endoscopy with biopsy and culture should be performed to confirm the diagnosis as well as *Candida* speciation. If candidiasis is confirmed, P.J. should be checked for medication adherence and potential drug interactions. If the patient is adherent and does not have malabsorption, posaconazole suspension or itraconazole solution should be considered. In addition, higher doses of fluconazole could be considered before the initiation of alternative IV therapy. Relapse is common in patients who do not receive secondary prophylaxis. Chronic suppressive therapy (fluconazole, 100–200 mg/day) could be considered in patients responsive to fluconazole therapy who have frequent or severe recurrent esophagitis; however, the risks of fluconazole resistance should be considered.[12]

Fungal Infections

John Cleary and Russell E. Lewis

CORE PRINCIPLES		CHAPTER CASES
1	Owing to increased numbers of immunocompromised patients, the use of invasive devices, and an aging patient population, invasive fungal infections are the fourth most common nosocomial infection.	
2	Yeast infections are generally easier to treat than mold infections. However, mortality is still significant for both types of infection, even when treated appropriately.	**Table 78-2**
3	Most common risk factors for acquiring mycotic infections include immunocompromised host, the use of broad-spectrum antibacterials, and	**Case 78-3 (Questions 1, 3)**

	breakdown of physical barriers including invasive catheterization.	
4	Diagnostic tools (ie, serum galactomannan or β-glucan) can be useful as monitoring parameters for therapeutic outcome assessment.	**Case 78-3 (Question 2)**
5	The Infectious Disease Society of America (IDSA) and the Mycoses Study Group are important sources for guidelines and evidence-based approaches to therapy.	**Case 78-5 (Question 1)**
6	Dermatophyte infection is most commonly associated with *Tinea* ringworm, and the most effective antifungal agents include itraconazole and terbinafine.	**Case 78-1 (Questions 1–3)**
7	Sporothrix is one of the most common fungal pathogens associated with subcutaneous infections. Amphotericin, terbinafine, and itraconazole are useful treatments.	**Case 78-2 (Questions 1–3), Figure 78-1**
8	Candida represents the most common cause of systemic fungal infection in hospitalized patients. Candidemia must be treated promptly and appropriately. Delay in treatment or failure to adhere to IDSA guidelines results in a significant increase in mortality. Fluconazole and echinocandins are the most recommended prophylaxis and therapies for disseminated candidiasis.	**Case 78-3 (Questions 1–4, 11), Tables 78-4–78-6**

9	Fluconazole, although reliable against *Candida albicans*, is less reliable against certain non-albicans Candida species, including *Candida glabrata* and *Candida krusei*.	**Case 78-3 (Question 5)**
10	Conventional amphotericin is associated with significant infusion-related adverse events, nephrotoxicity, and electrolyte abnormalities. Consequently, other agents, including lipid-based amphotericin B, triazoles, and echinocandins, are drugs of choice for most deep-seated fungal infections.	**Case 78-3 (Questions 6–10), Table 78-3**
11	In patients with yeast identified in urine, the selection of drug therapy for a simple candiduria versus organ infection as a result of disseminated candidiasis is complicated by difficulties with diagnostics.	**Case 78-4 (Question 1)**
12	Blastomycosis, histoplasmosis, and coccidioides are associated with endemic infection from specific geographic areas. Long-term treatment with polyenes and/or azole antifungals is useful in the management of these diseases.	**Case 78-5 (Questions 1–3)** **Case 78-6 (Questions 1–3)** **Case 78-7 (Questions 1–3), Figures 78-2–78-4, Table 78-7**
13	Aspergillus is the most significant fungal pathogen associated with severely immunocompromised patients. Aggressive, immediate treatment with voriconazole alone or in combination with other antifungals is the most	**Case 78-8 (Questions 1–3), Figure 78-5, Table 78-8**

	effective therapy for disseminated disease.	
14	*Cryptococcus neoformans* is associated with opportunistic infection, particularly in acquired immunodeficiency syndrome (AIDS), and the central nervous system (CNS) is a common site of infection. Initial treatment of meningitis in AIDS should include amphotericin B plus flucytosine, followed by long-term fluconazole.	**Case 78-9 (Questions 1–3)**

INTRODUCTION

Mycotic (fungal) infections are now the fourth most commonly encountered nosocomial infection. Attributable mortality associated with invasive yeast infections can approximate 40%, whereas molds typically double that observed rate (ie, invasive aspergillosis). This increase can be attributed, in part, to the growing numbers of immunocompromised hosts as a result of organ transplants, cancer-chemotherapy–associated neutropenia, and acquired immunodeficiency syndrome (AIDS). This chapter reviews the mycology, diagnosis, and pharmacotherapeutics for common mycotic infections. For a more in-depth presentation of the basic biology of fungi, as well as the epidemiology, pathogenesis, immunology, diagnosis, and monitoring of mycotic infections, see *Clinical Mycology*.[1] Referred to Chapter 65, Central Nervous System Infections; Chapter 66, Endocarditis; Chapter 70, Intra-Abdominal Infections; Chapter 73, Osteomyelitis and Septic Arthritis; Chapter 75, Prevention and Treatment of Infections in Neutropenic Patients; Chapter 76, Pharmacotherapy of Human Immunodeficiency Virus Infection; and Chapter 77, Opportunistic Infections in Patients Living With HIV, for detailed pharmacotherapy in these human pathologies.

MYCOLOGY

Morphology

The pathogenic fungi that infect humans are nonmotile eukaryotes that are reproduced by sporulation, and they exist in two forms: filamentous molds and unicellular yeasts. These forms are not mutually exclusive, and depending on the growth conditions, a fungus may exist in one or even both of these forms (**Table 78-1**).

Table 78-1
Organism Classification

Hyphae (Molds)
Hyalohyphomycoses *Aspergillus* species, *Pseudallescheria boydii* *Dermatophytes*: *Epidermophyton floccosum, Trichophyton* species, *Microsporum* species **Phaeohyphomycoses** *Alternaria* species, *Anthopsis deltoidea*, *Bipolaris hawaiiensis, Cladosporium* species, *Curvularia geniculata*, *Exophiala* species, *Fonsecaea pedrosoi*, *Phialophora* species, *Fusarium* species **Zygomycetes** *Rhizopus* spp., *Mucor* spp., *Rhizomucor* spp. *Absidia corymbifera*
Dimorphic Fungi
Blastomyces species, *Coccidioides* species, *Paracoccidioides* species, *Histoplasma* species, *Sporothrix* species
Yeasts
Candida species, *Cryptococcus neoformans*

The dimorphic fungi (eg, *Histoplasma capsulatum* and *Blastomyces dermatitidis*) grow as a mold in nature (27 °C) but quickly convert to the pathogenic yeast form after infecting the host (37 °C). This mycelium-to-yeast conversion is an important factor in the pathogenesis of disease caused by these organisms. Other pathogenic fungi, such as *Aspergillus* species, grow only in a mold

form, whereas *Cryptococcus neoformans* usually grows in a yeast form. *Candida* species grow with a modified form of budding, whereby newly budded cells remain attached to the parent cells and form pseudohyphae. Fungi are aerobic and are easily grown on routine culture media similar to that used to grow bacteria. Most fungi grow best at 25 °C to 35 °C. Fungi that cause only cutaneous and subcutaneous disease grow poorly at temperatures >37 °C. This temperature-selective growth explains, at least in part, why these organisms rarely disseminate from a primary focus in the skin or subcutaneous tissues.

Classification

Fungal infections are best classified by the area of the body infected (**Table 78-2**). Superficial mycoses involve only the outermost keratinized layers of the skin (stratum corneum) and hair. The cutaneous mycoses extend deeper into the epidermis and may also infect the nails. The subcutaneous mycoses infect the dermis and subcutaneous tissues; entry into these sites is by the inoculation or implantation of dirt or vegetative matter. The systemic mycoses cause disease of the internal organs of the body. Standard definitions that are useful in daily patient care for invasive fungal infections have been developed for epidemiologic and clinical trials. The guidelines are referenced under each infection. The respiratory tract is the most common primary portal of entry, and lung infection may be symptomatic or asymptomatic. Systemic infection with *Candida* usually results from a primary focus on the gastrointestinal (GI) tract or skin. In each case, the organism may spread hematogenously from the primary focus throughout the body, resulting in disseminated disease. The opportunistic mycoses occur primarily in the immunocompromised host and require immediate and aggressive treatment. The list of fungi that cause opportunistic infection has expanded, especially with the AIDS epidemic; however, the now commonplace use of highly active antiretroviral therapy has resulted in some decrease in this incidence.[2] The nonopportunistic

fungi (primary pathogens) usually cause disease in the immunologically normal host. Some primary pathogens, however, result in unique clinical syndromes when infection occurs in the immunocompromised host, such as histoplasmosis in AIDS.[1]

Table 78-2
Clinical Classification of Mycoses

Classification	Site Infected	Example	Potential Gene Deficiency
Superficial	Outermost skin and hair	Malasseziasis (tinea versicolor)	
Cutaneous	Deep epidermis and nails	Dermatophytosis	
Subcutaneous	Dermis and subcutaneous tissue	Sporotrichosis	
Systemic	Disease of more than one internal organ		
Opportunistic		Candidiasis	Mannose-binding lectin-1 Toll-like receptor 4
		Cryptococcosis	Dectin-1
		Aspergillosis	
		Mucormycosis	
Nonopportunistic		Histoplasmosis	
		Blastomycosis	
		Coccidioidomycosis	Interferon-γ receptor 1 Dectin-1 Mannose-binding lectin-1

Pathogenesis of Infection

ENDOGENOUS

Fungal infection can be acquired from both exogenous and endogenous sources. The only pathogenic fungi identified as commensals within the human microbiome are *Pityrosporum orbiculare*, which causes the noninflammatory superficial condition of tinea versicolor, and *Candida* species. Infections with these yeasts primarily develop from the patient's own normal flora (endogenous infection). These endogenous fungal infections of the skin or mucous membranes generally occur when host resistance is lowered, and the organism proliferates in high numbers. Excess heat and humidity, oral contraceptive use, pregnancy, diabetes, malnutrition, and immunosuppression facilitate endogenous local infection by both *Pityrosporum* and *Candida*. Systemic candidal infections occur in the immunocompromised or genetic deficient host (see **Table 78-2**)[3],[4]

when the organism colonizing the patient's skin or GI tract disseminates hematogenously throughout the body.

EXOGENOUS

Exogenous infections occur when the fungus is acquired from an environmental source. In the case of dermatophytes (ringworm fungi), the organism can be acquired from dirt, animals, or another infected individual. The subcutaneous mycoses result from direct inoculation of infected material, often a thorn or other vegetable matter, through the skin. Infections of the skin and subcutaneous tissues by *Aspergillus* and zygomycetes (eg, *Rhizopus*, *Absidia*, and *Mucor*) have resulted from contaminated wound dressings and cast materials.[1,5] Drug-induced disease has been observed secondary to *Saccharomyces cerevisiae* (nutraceutical) administration to healthy and immunocompromised patients or secondary to the administration of a contaminated sterile product (ie, *Exserohilum rostratum*).

Exogenous fungi colonized or carried on the hands of health care workers can infect patients; therefore, handwashing is emphasized for health care workers, particularly in critically ill patients.[6] Other than candidal infections, the systemic mycoses are primarily the result of inhalation of dust contaminated by the infectious spores, with a primary focus on infection in the lungs.

If local or systemic host defenses do not control the primary infection, the organism can spread hematogenously to other organs. Some of the systemic mycoses have defined geographic (endemic) areas where the fungus is more commonly encountered. For example, histoplasmosis and blastomycosis occur most often in the regions of the Red, Mississippi, and Ohio River valleys, whereas coccidioidomycosis is endemic to the southwestern United States and the Central Valley of California.

Host Defenses

Host defenses against fungal infection involve both nonimmune (also known as nonspecific or natural resistance) and immune (also known as specific or acquired resistance) mechanisms. Nonimmune resistance plays a primary role in preventing colonization and invasion of a susceptible tissue. The normal bacterial flora of the skin and mucous membranes prevent colonization (colonization resistance) by more pathogenic bacteria and fungi. Patients treated with broad-spectrum antibiotics are at a greater risk for colonization and infection by fungi. The barrier function of the intact skin and mucous membranes is also an important defense. Skin defects (intravenous [IV] catheters, burns, surgery, or trauma) are risk factors for local invasion and fungemia, especially with *Candida* species. The translocation of yeast from the gut into the peritoneum during the trauma of a motor vehicle accident or post-GI surgery is also commonly associated with these infections. When these physical barriers are breached, the polymorphonuclear leukocyte (neutrophil) and monocytes along with defensive lectins (ie, mannose-binding protein) provide early host defense. The antifungal activity of neutrophils not only involves phagocytosis and intracellular killing but also can include extracellular killing by secreted lysosomal enzymes. Neutropenia is the most common neutrophil defect predisposing to fungal infection, but functional defects of neutrophils, such as those occurring in patients with chronic granulomatous disease of childhood and myeloperoxidase deficiency, have also been associated with an increased frequency of fungal infections, especially with *Candida* and *Aspergillus*. Finally, endothermy/homeothermy and ultimately febrile responses are potent nonspecific immune defenses.

Antibody and complement have a potential role in the prevention of certain fungal infections, but they are not the primary effectors of acquired resistance. Cellular immunity, mediated by antigen-specific T lymphocytes, cytokines, and activated macrophages, is the primary acquired (immune) host defense against fungi. Patients with defective cellular immunity (eg, immunosuppressed organ transplant recipients, patients with lymphoma and leukemia, patients with AIDS, and those treated with corticosteroids or cytotoxic agents) are at the

greatest risk for fungal infection. Severe immunodeficiency often results in poor therapeutic outcome despite appropriate antifungal therapy. An additional factor associated with an increased risk for fungal infection is the use of total parenteral nutrition (TPN).[1] Interestingly, patients with specific T-cell dysfunction (ie, human immunodeficiency virus [HIV] infection) appear to be at an isolated risk for mucosal *Candida* infection, but not systemic infections.

ANTIMYCOTICS

Mechanisms of Action

Table 78-3 lists the U.S. Food and Drug Administration (FDA)-approved topical and systemic antimycotics for the treatment of fungal infections. Griseofulvin and potassium iodide have limited clinical utility and are not used to treat systemic fungal infections. Griseofulvin inhibits growth by inhibiting fungal cell mitosis caused by the polymerization of cell microtubules, thereby disrupting mitotic spindle formation. It has activity only against the dermatophyte fungi. The antifungal mechanism of potassium iodide is unclear. It is effective only in the treatment of lymphocutaneous sporotrichosis.

Table 78-3
Antifungal Agents Approved for Use

Agent (Brand Name)	Formulation
Systemic Agents	
Amphotericin B (Abelcet®, AmBisome®, Amphotec®)	IV
Amphotericin B-deoxycholate (generic)	IV
Anidulafungin (Eraxis®)	IV
Caspofungin (Cancidas®)	IV

Fluconazole (Diflucan®)	IV, tablet, oral suspension
Fluorocytosine (Flucytosine) (Ancobon®)	Capsule
Griseofulvin (generic)	Tablet, oral suspension
Isavuconazole (Cresemba®)	IV, oral capsule
Itraconazole (Sporanox®)	IV, capsule, oral solution
Ketoconazole (Nizoral®)	Tablet
Micafungin (Mycamine)	IV
Posaconazole (Noxafil®)	IV, oral suspension, oral gastroresistant tablet
Potassium iodide	Solution
Terbinafine (Lamisil®)	Tablet, oral granules
Voriconazole (Vfend®)	IV, tablet, oral suspension
Topicals, Class I	
Amphotericin B	Cream, lotion, ointment, oral suspension[a]
Butenafine (Lotrimin Ultra®)	Cream
Butoconazole (Gynazole®)	Vaginal cream
Ciclopirox (Loprox®)	Cream, gel, lotion, shampoo, solution, suspension
Clioquinol (Vioform®)	Cream, ointment
Clotrimazole	Cream, lotion, lozenge, solution, tablet, vaginal cream
Econazole (Spectazole®)	Cream
Ketoconazole (Nizoral®)	Cream, foam, gel, shampoo
Miconazole	Aerosol liquid and powder, buccal tablet, cream, lotion, ointment, powder, suppository, vaginal tablet
Naftifine (Naftin®)	Cream, gel
Nystatin	Cream, mouthwash, ointment, powder, suspension, tablet
Oxiconazole (Oxistat®)	Cream, lotion

Povidone iodine	Aerosol, douche, gel, ointment, solution, suppository
Sodium thiosulfate (Exoderm®)	Lotion
Sulconazole (Exelderm®)	Cream, solution
Terbinafine (Lamisil®)	Cream, spray
Terconazole (Terazol® 7)	Cream, suppository
Tioconazole (Vagistat®)	Ointment
Tolnaftate (generic)	Aerosol, cream, gel, powder, solution
Undecylenic acid	Powder

IV, intravenous.

[a]No longer available in the United States.

The 12 antifungal drugs used commonly for systemic disease fall into five structural classes that act by four mutually exclusive mechanisms. Amphotericin B (AmB) and nystatin (a polyene macrolide) act principally by binding to ergosterol in the fungal cell membrane, effectively creating pores in the cell membrane and leading to the depolarization of the membrane and cell leakage.[7] AmB binds with greater affinity to ergosterol than to cholesterol.[8] This phenomenon is believed to be mediated through both hydrophilic hydrogen bonding and hydrophobic, nonspecific van der Waals forces. Investigations using P(^{32}) nuclear magnetic resonance spectroscopy document that the presence of the double bond in the side chain of ergosterol (not present in cholesterol) accounts for the greater affinity of AmB for ergosterol.[7] AmB, however, also binds to sterols of mammalian cells (ie, cholesterol), which may account for most of the toxic effects of AmB or reduced toxicity (ie, circulating cholesterol). Alteration in the lipid content of the pathogen's membrane may play a role in the development of resistance,[9] although other factors are also important.[10] The fungicidal effects of AmB are, however, not only owing to cell leakage resulting from ergosterol binding, but also owing to immune stimulation and oxygen-dependent killing.[8],[11]

5-Flucytosine, a fluorinated cytosine analog, acts principally by inhibiting nucleic acid synthesis. It is actively transported into susceptible cells by the enzyme cytosine permease, where it is deaminated to the toxic metabolite 5-fluorouracil. Fluorouracil, when converted to 5-fluorouridine triphosphate, functions as an antimetabolite. It is incorporated into fungal RNA, where it is substituted for uracil and thereby disrupts protein synthesis. 5-Fluorouracil can also be converted to fluorodeoxyuridine monophosphate, which inhibits thymidylate synthase and thus disrupts DNA synthesis.[12]

The azole antifungals and the allylamines (naftifine and terbinafine) inhibit sterol biosynthesis by interference with either cytochrome (CYP) P450–dependent lanosterol C14-demethylase (azoles) or squalene epoxidase (allylamines), critical enzymes in the biosynthesis of ergosterol.[13],[14] The superior affinity of the triazoles (fluconazole, itraconazole, isavuconazole, posaconazole, and voriconazole) for fungal versus mammalian enzymes, as compared with the imidazoles (ketoconazole and miconazole), accounts for their reduced toxicity and improved efficacy.[13] The consequence of sterol biosynthesis inhibition is a faulty cell membrane with altered permeability. In general, the allylamines and older azoles are fungistatic. The newer triazoles (voriconazole and posaconazole) demonstrate fungicidal activity against some fungal species. The clinical relevance of in vitro fungicidal versus fungistatic action is the subject of considerable debate. Nevertheless, it seems logical that fungicidal action, if it can also be achieved in vivo, is preferred in immunosuppressed hosts.[15]

Lipopeptides, which are potent antifungal agents, include the structural class of echinocandins (anidulafungin, micafungin, and caspofungin). All share a common mechanism. They act by interfering with 1,3-β-D-glucan, preventing the synthesis of essential cell wall polysaccharides that protect the cell from osmotic and structural stresses. The result is inhibition of fungal cell wall biosynthesis. Targeting the cell wall (as opposed to the cell membrane, which is the target of polyene, azole, and allylamine

antifungals) imparts greater selectivity for fungal versus mammalian cells; thus, echinocandins class of antifungals has fewer toxicities than other antifungal classes.[16]

Antifungal Spectrum and Susceptibility Testing

The Clinical and Laboratory Standards Institute (CLSI) recommends standardized broth dilution (M27-A3) and disk diffusion (M44-A2, M44-S3, and M51-A) methods for determining in vitro antifungal susceptibilities for yeasts.[17] These methods stipulate test medium, inoculum size and preparation, incubation time and temperature, end point reading, and quality control limits for AmB, flucytosine, fluconazole, ketoconazole, and itraconazole. Minimum inhibitory concentration (MIC) values for use in clinical interpretation are specified for fluconazole, voriconazole, itraconazole, flucytosine, and the echinocandins against *Candida* species after 24 hours of incubation. For azoles, a susceptible-dose-dependent (S-DD) break point was developed based on data supporting a trend toward better response with higher drug concentrations for isolates with higher MIC.[18] The fluconazole S-DD range is 4 to 8 µg/mL for *C. albicans*, *Candida parapsilosis*, and *Candida tropicalis* and ≤32 mg/L for *C. glabrata*. Itraconazole and voriconazole S-DD ranges are 0.25 to 0.5 mg/L for *C. albicans*. Owing to the rapid development of resistance and limited data on correlation of MIC with outcome for flucytosine monotherapy, proposed interpretive break points for this agent are based on a combination of historic data and results from animal studies. *Candida* isolates with a flucytosine MIC ≤4 µg/mL are considered susceptible, and isolates with MIC >16 µg/mL are considered resistant. Limitations of the M27-A methodology have precluded the development of AmB interpretive break points nor have interpretive criteria been proposed for ketoconazole MIC. Candida are generally susceptible to MIC >0.25 µg/mL and resistant to >1 µg/mL, except for *C. parapsilosis* and *Candida guilliermondii* that have higher susceptibility (>2 µg/mL) and resistant (>8 µg/mL) values. Commercial kits are available for antifungal susceptibility

testing, which use broth microdilution, colorimetric, and agar-based techniques.[19–21] The University of Texas Health Science Fungal Testing Laboratory has historically tested fungi susceptibilities and reports current break points and epidemiologic cutoff values.

An E-Test (AB Biodisk; Piscataway, NJ) is a commercially available antifungal gradient strip. Difficulties in end point determination using this method result from frequent, nonuniform growth of the fungus on the agar medium; yet, when properly performed, correlation between the E-Test and M27-A methods has been satisfactory for the azole antifungal agents against most *Candida*.[19] Other techniques under development for antifungal susceptibility testing for yeasts include flow cytometry and direct measurement of alterations in ergosterol synthesis.[20] Flow cytometry detects the activity of the test antifungal drug through identification of subtle dosage–response effects on specific cell parameters as cells within the prepared inoculum pass through a beam of light. Test results may be available in as few as 4 hours. Interlaboratory reproducibility or correlation between test results and clinical outcomes has not been well studied.[21]

The CLSI-recommended standardized broth dilution method for determining in vitro antifungal susceptibilities for certain spore-producing molds, namely *Aspergillus* species, *Fusarium* species, *Rhizopus* species, *Pseudallescheria boydii*, and *Sporothrix schenckii*, is the M38-A2 method.[15] An E-Test to evaluate mold susceptibilities is also commercially available (AB Biodisk) and correlates well with the CLSI M38-A method for AmB and itraconazole.[22] Colorimetric microdilution, flow cytometry, and agar-based testing methods are under development. Despite these recent advances, the determination of in vitro susceptibilities or resistance in clinical practice is of limited utility and not readily available for yeasts or molds in most institutions.

Susceptibility testing for clinical isolates is not routinely recommended because susceptibility is usually predictable. However, published data on the susceptibility of the identified species of yeasts or molds should guide the clinician’s therapeutic choice. Clinical isolates from patients failing high-dose therapy (ie,

refractory oral pharyngeal candidiasis) or unusual pathogenic yeasts in patients with AIDS can be sent for testing.[20] Testing should be performed in a laboratory where the staff is trained in mycoses. Despite these limitations, certain patterns are common. First, AmB has broad in vitro activity and clinical efficacy against the yeasts and filamentous molds. The echinocandins have cidal activity in vitro versus *Candida* species and static activity for *Aspergillus* species; they are not active in vitro against *Cryptococcus* species and many endemic mycoses.[23] The azole antifungals are generally reliable against the yeasts and most dimorphic fungi. Additionally, itraconazole, voriconazole, and posaconazole have excellent in vitro activity against *Aspergillus* species, with associated clinical efficacy. Unlike other azoles, posaconazole and isavuconazole have some activity in vitro and reported clinical evidence of efficacy against zygomycetes, for which previously only AmB formulations were therapeutic options.[24,25]

Routine susceptibility testing of fluconazole, voriconazole, and an echinocandin against *C. glabrata* is increasingly recommended, especially for isolates from blood normally sterile fluids, tissue, or abscess owing to recent reports of increasing echinocandin and multidrug resistance.[26–28] Additionally, any patient with invasive disease and clinical failure of initial therapy should be considered for susceptibility following consultation with an experienced microbiologist.

New Frontiers for Antifungal Therapy

Various investigative efforts have been directed toward enhancing efficacy, reducing the toxicity, and improving the oral bioavailability of older antifungal drugs. Aerosol delivery of AmB products, itraconazole, voriconazole, and caspofungin in immunocompromised patients has been investigated for the prevention of invasive pulmonary aspergillosis. Reduction in invasive pulmonary aspergillosis was demonstrated in a randomized, placebo-controlled trial of aerosolized liposomal AmB.[29] Additional well-designed clinical

trials are still needed to establish the role of aerosolized delivery of antifungal agents. Optimal antifungal dose and nebulized system required for effective prophylaxis have yet to be established compared with traditional GI regimens (**Table 78-4**).[29–31]

Table 78-4
Antimycotic Prophylaxis Regimens and Approximate Costs

Agent	Dose/Day	Formulation	Recommended Regimen	Cost ($)/day
Selective GI Decontamination				
Amphotericin B	400 mg	Oral suspension	Swish and swallow qid	9.75
Nystatin	4–12 million units	Oral suspension	Swish and swallow qid	38.50–115.25
Systemic				
Clotrimazole	30–80 mg	Troche	tid–qid	125–450
Ketoconazole	200–400 mg	Oral	Daily	0.75–1.50

Identification of new antifungal compounds has been challenging. One significant barrier is that both mammalian cells and fungal cells are eukaryotes and share many similar biochemical processes, unlike bacterial cells, which are prokaryotes. Traditionally, the drug discovery process depended on the ability to detect compounds (either natural products or synthetic compounds) that selectively inhibit or destroy fungal cells. This process is accomplished by either or both of two approaches: (a) the evaluation of existing compounds (natural or synthetic) for potentially useful antifungal activity and (b) the design and synthesis of new compounds that selectively block fungal targets. Recent advances in genomic sequencing of *C. albicans*, *C. glabrata*, *Aspergillus fumigatus*, *Rhizopus oryzae* (delmar), and *C. neoformans* have facilitated the search for new targets. Other less conventional drug discovery approaches include targeting known traditional virulence factors (eg, adhesions and secreted enzymes). This approach is based on the principle that killing of the microbe need not occur for an anti-infective agent to be

efficacious. Promising lead compounds include nikkomycins, sordarins, lytic peptides, hydroxypyridones, and cathelicidins.[32–35]

SUPERFICIAL AND CUTANEOUS MYCOSES

Tinea Pedis: Treatment

CASE 78-1

QUESTION 1: C.W., a 28-year-old male construction worker, is evaluated for a chronic case of "athlete's foot." He wears boots all day at work and notes intense itching of both feet throughout the day. He has been using tolnaftate powder for 1 week with no real therapeutic benefit. On examination, the web spaces between all the toes are white, macerated, and cracked. A few vesicles are also present over the dorsum of the foot at the base of the toes. Scrapings of the lesions examined as a potassium hydroxide (KOH) preparation reveal branching, filamentous hyphae compatible with a dermatophyte infection. The diagnosis of athlete's foot is made.

What therapeutic options are available for C.W.?

Selection of antifungal therapy should be based on the extent and type of infection.

Superficial or cutaneous infections should initially be approached topically. Any follicular, nail, or widespread (>20% of body surface area) infection should be treated systemically under medical supervision owing to poor penetration of topical applications. Topical antifungals have been reviewed as a class by the FDA advisory review panel on over-the-counter (OTC) antimicrobial drug products and on an individual basis as newer products have been released. To receive a class I recommendation, each agent (or combination) must have been tested in well-designed clinical trials that show that the drug is microbiologically and clinically effective against dermatophytosis or candidiasis with insignificant toxicity (irritation). Class I agents are listed in **Table 78-3**. Class II agents (camphor, candicidin, coal tar, menthol, phenolates, resorcinol, tannic acid,

thymol, and tolindate) are considered to have higher risk–benefit ratios associated with their pharmacotherapy. Class III agents (benzoic acid, borates, caprylic acid, oxyquinolines, iodines, propionic acid, salicylates, triacetin, and gentian violet) lack adequate scientific data to determine efficacy. Topical therapy with any class I agent applied twice daily to the affected area for 2 to 6 weeks should be adequate. Therapy should be titrated to response.

C.W. could continue tolnaftate powder for 2 to 6 weeks or switch to an antifungal cream or lotion (eg, miconazole and terbinafine), and these products should be applied to the web spaces between all the affected toes twice daily. C.W. should also be careful to use nonocclusive footwear (eg, cotton rather than synthetic fiber socks and leather rather than vinyl boots). Application of an absorbent or antifungal powder to his footwear would also be helpful (see Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders).

Tinea Unguium (Onychomycosis): Treatment

Case 78-1, Question 2: If C.W. also had an infection of the toenail (onychomycosis), what additional therapy could be offered to him?

Onychomycosis is typically caused by a dermatophyte, a hyphal fungi, or *Candida*.

Nail scrapings and culture should be performed to help plan initial therapy. Once culture results are known, therapy can be initiated with either terbinafine 250 mg/day or itraconazole 200 mg/day for 6 (fingernail) to 12 (toenail) weeks. In some cases, however, successful therapy of tinea unguium can require 3 to 6 months for fingernails and 6 to 12 months for toenails. Therapy should be considered successful when several millimeters of healthy nail have emerged from the nailfold to the margin of the infected nail or when a 25% reduction in the size of the infected site has been achieved.

For dermatophyte nail or paronychial infections, griseofulvin therapy could be used if an azole or allylamine is contraindicated. Griseofulvin (microsized or ultramicrosized) administered orally at 10

mg/kg/day and titrated to response should be effective.[25] Owing to the large doses given for prolonged periods, C.W. should be monitored closely at each prescription refill for signs and symptoms of adverse reactions. The most common adverse events associated with terbinafine or itraconazole are headache, rash, and GI distress. Griseofulvin is more toxic, often causing hypersensitivity (urticaria, angioedema, and type II hypersensitivity reactions), photosensitivity dermatitis, GI distress, and neurologic complications (headache, paresthesias, and altered sensorium).[25]

Antimycotic pulse therapy is a novel approach to the treatment of onychomycosis. An FDA-approved alternative to daily therapy can now include a course of itraconazole 200 mg twice daily for 1 week in 2 consecutive months for fingernail infections. Double-blind, placebo-controlled trials revealed that this regimen was associated with a 77% clinical response and 73% mycologic response.[36] Overall responses and toxicity to therapy were more desirable with pulse regimens than with traditional regimens. Comparative studies demonstrate promising results for itraconazole pulse therapy for toenail infections[37] and fluconazole pulse therapy administered as a 150- to 450-mg dose once weekly for up to 12 months for mild disease.[38],[39] Relapse rates after pulse (intermittent) terbinafine for 4 months have been frequent, and longer courses of therapy are under study to enhance long-term efficacy.[40] Longer courses of therapy are being evaluated.

Removal of the nail as the sole therapy is not recommended because of the high relapse rate without concomitant systemic therapy. Likewise, IV antifungals are not indicated.

Case 78-1, Question 3: Describe the role of corticosteroids, antibacterials, or other additives to the antimycotic regimen in C.W.

Many patients with superficial, cutaneous, or nail fungal infections will have local inflammation and secondary bacterial infections. Inflammation is primarily a type IV hypersensitivity reaction. Topical corticosteroids in conjunction with antifungals can relieve itching and

erythema secondary to inflammation. Bacterial (*Proteus* or *Pseudomonas* species) superinfection can also occur in these inflamed or macerated areas requiring concomitant topical antibacterial therapy. Pharmaceutical manufacturers of OTC preparations often combine a drying agent or astringent (eg, alcohol, starch, talc, and camphor) to their preparations to increase the desquamation of the stratum corneum. Hyperhidrosis also can be relieved by these pharmaceutical additions. Such combination treatments should not be used routinely, however, because they increase the risk of toxicity and do not increase efficacy. If required for symptomatic relief, they should be used only for the initial days of treatment.

The affected web spaces between C.W.'s toes are macerated and cracked, and vesicles are present at the base of his toes. A topical corticosteroid cream will probably facilitate the healing process and make him more comfortable during the first few days of antifungal therapy. The selection of topical corticosteroid formulations is presented in Chapter 39, Dermatotherapy and Drug-Induced Skin Disorders.

SUBCUTANEOUS MYCOSES

Sporotrichosis

TREATMENT OPTIONS

CASE 78-2

Question 1: O.M., a 62-year-old male, has had a painless, slowly enlarging ulcer on his left hand for the past 4 months. He is an avid gardener but can identify no antecedent local trauma. The primary lesion began as a red papule that slowly enlarged and then ulcerated. At the same time that the ulcer developed, O.M. also noted painless, red nodules that spread proximally up his arm. He denies any chills, fever, weight loss, or cough. The ulcer has slowly enlarged despite the daily application of a povidone iodine ointment and 2

weeks of cephalexin treatment. On physical examination, O.M. is afebrile. A 1.5 cm^2 ulcer is present on the dorsum of the left hand. Extending proximally from the ulcer are a palpable cord and multiple nontender, erythematous nodules distributed linearly up the forearm, elbow, arm, and axilla. A culture of this ulcer obtained 4 weeks ago is now growing *S. schenckii*.

What is the recommended therapy for O.M.?

S. schenckii is the dimorphic fungi found in the soil and on many plants. Infection is usually secondary to inoculation into the skin from a thorn or sharp plant matter. *S. schenckii* infection most commonly causes lymphocutaneous disease (**Fig. 78-1**) as illustrated by this case. Rarely, extracutaneous disease may occur and usually involves the lungs, bones, or joints.

Figure 78-1 Lymphocutaneous sporotrichosis.

HEAT TREATMENT

In the 1930s and 1940s, local heat was applied to very mild plaque or lymphocutaneous disease. Germination rates of this dimorphic fungus can actually be decreased by increased temperature, and heat therapy 1 hour/day for 3 months is effective in 90% of patients with plaques (very mild disease).[41] Heat treatment could be particularly useful in pregnant patients when pharmacotherapy may be contraindicated.

ITRACONAZOLE

Itraconazole is more active in vitro against *S. schenckii* than other imidazoles or saturated solution of potassium iodide. Saturated solution of potassium iodide is seldom used for therapy secondary to treatment-limiting toxicity. Cure rates for sporotrichosis cutaneous and lymphocutaneous disease are >90% with itraconazole 100 to 200 mg/day for 3 to 6 months. For extracutaneous disease, higher dosages of itraconazole (200 mg twice a day [bid]) for 1 to 2 years achieve response rates of 81%, but relapse frequently occurs (27%) after therapy is stopped.[41],[42] Itraconazole is well tolerated in these patients. Patients with extracutaneous disease who are unable to tolerate the higher itraconazole dosages or whose disease continues to progress should be treated with AmB or a lipid-based amphotericin product. A total dose of 2.0 to 2.5 g is most often recommended if conventional AmB is used. Although voriconazole, posaconazole, and ravuconazole demonstrate in vitro activity against *S. schenckii* (albeit less than itraconazole), their role in the treatment of sporotrichosis has not been defined.[43] Neither ketoconazole nor fluconazole is effective in the treatment of sporotrichosis.

TERBINAFINE

Terbinafine has a good in vitro activity against *S. schenckii* and has been used clinically with some success.[44] An unpublished clinical trial comparing 250 or 500 mg bid for 3 months for lymphocutaneous disease appeared clinically equivalent to itraconazole. Adverse reactions include GI distress (dysgeusia, dyspepsia, and diarrhea), skin rash, and weight gain.

Therefore, in the case of lymphocutaneous disease, itraconazole 100 mg/day for a minimum of 3 months is the treatment of choice. If significant improvement is not observed in the first 6 weeks, the itraconazole dosage should be increased to 200 mg/day and continued for 6 months or until both the ulcer and lymphangitis have resolved. Most patients will respond to this dosage, but an occasional patient may require dosages of 300 or 400 mg/day.

Itraconazole Dosing

Case 78-2, Question 2: What instructions should O.M. receive for taking his antifungal agent?

The peak serum concentrations of itraconazole capsules are ninefold higher when the drug is taken with food (0.18 µg/mL with food vs 0.02 µg/mL in fasting subjects).[45] The influence of food on absorption appears to be dependent on food type. High-carbohydrate meals decrease the absorption of itraconazole, and high-lipid-content meals increase itraconazole absorption.[46] Patients who have difficulty eating (eg, patients with AIDS and those with cancer receiving antineoplastic therapy) or with hypochlorhydria may not absorb a sufficient amount from the capsule to achieve therapeutic plasma concentrations after a typical oral dose.[47] Although itraconazole manifests nonlinear serum pharmacokinetics (ie, administering the total dose in two divided doses is associated with higher peak serum concentrations than a single larger dose), there is no clinical benefit in splitting the dose. Therefore, O.M. could be instructed to take his itraconazole capsule with his highest-fat-content meal of the day or itraconazole solution could be substituted to improve absorption.

Itraconazole oral solution is a cyclodextrin formulation that has 55% bioavailability in a fed patient; this increases in a fasting patient (**Table 78-5**). Furthermore, bioavailability of this formulation is not affected by the level of gastric acidity. Average serum concentration in a cohort of patients with advanced HIV infection was 2.7 µg/mL

after a 28-day twice-daily dosing regimen.[48] O.M. should take his itraconazole solution on an empty stomach bid if this formulation is selected.

AUC, area under the concentration–time curve; C_{max}, maximum concentration; CSF, cerebrospinal fluid; ND, no data; T_{max}, time of maximum concentration; $t_{1/2}$, half-life.

[a]Given parameters are estimated from the administration of currently recommended doses. Miconazole (MCZ) 7.4–14.2 mg/kg/day (500–1000 mg) parenterally; ketoconazole (KTZ) 2.8 mg/kg/day orally (200 mg); itraconazole (ITZ) 1.4–2.8 mg/kg/day orally (100–200 mg); fluconazole (FCZ) 0.7–1.4 mg/kg/day orally; voriconazole (VCZ) and posaconazole (PCZ) 400 mg twice-daily orally; or 300 mg twice-daily day 1, then 300 mg daily; isavuconazole (ICZ) 200 mg (372 mg isavuconazonium sulfate) three times daily for 48 hours, then 300 mg daily anidulafungin (AFG) 200 mg parenterally; caspofungin (CFG) 70 (50) mg parenterally on day 1 (2–14); micafungin (MFG) 70 mg parenterally; flucytosine (5FC) 150 mg/day parenterally; and terbinafine (TBF) 250 mg/day orally.

[b]With meals (fasting), absorption altered by gastric acidity.

[c]Dose-dependent and/or infusion-dependent.

[d]Absorption decreased when administered with high-fat meal; C_{max} and AUC reduced by 34% and 24%, respectively.

Case 78-2, Question 3: How would instructions for taking itraconazole capsules be modified if O.M. were achlorhydric as a result of medications or AIDS gastropathy? Should azole serum concentrations be monitored for an assessment of efficacy?

Itraconazole capsules, as with ketoconazole, require an acidic environment for dissolution and absorption. Thus, patients who are achlorhydric, as a result of medications, surgery, or underlying disease (eg, AIDS gastropathy), may not absorb itraconazole capsules adequately.[47],[49] The use of ketoconazole in achlorhydric patients has historically required concomitant administration of 4 mL, 0.2 N hydrochloric acid aqueous solution. Etching of tooth enamel by the acid can occur; thus, other alternatives have been explored. The administration of ketoconazole and itraconazole with a low pH liquid (eg, 8–16 fluid ounces of a carbonated cola beverage or orange juice) improves absorption in 65.2% of healthy patients who are achlorhydric or taking H_2-blockers.[49] Refer to Azole–Drug Interactions section for more detailed information on problematic therapeutic combinations.

Voriconazole does not require an acidic environment for adequate oral absorption, but voriconazole should be administered 1 hour before or after meals because high-fat meals may reduce voriconazole serum concentrations.[50] In contrast, posaconazole plasma concentrations are fourfold higher after administration with food or a high-fat nutritional supplement. A newer formulation of posaconazole, which releases the drug in a pH-dependent manner in the duodenum, is not dependent on low gastric pH for dissolution and does not require administration with food to achieve therapeutic levels.[51–53] Isavuconazole is unique among triazole antifungals because it is administered IV or orally as a prodrug (isavuconazonium sulfate), which is rapidly cleaved by plasma esterases to the active antifungal, isavuconazole. Absorption of the prodrug is relatively complete (>90% bioavailability) and does not require low gastric pH or coadministration with food. IV isavuconazonium is water-soluble and, unlike voriconazole or posaconazole parenteral formulations, is not solubilized in hydroxypropyl-β-cyclodextrin.

Because serum ketoconazole, itraconazole, and voriconazole concentrations <0.25 to 1.0 μg/mL have been associated with an increased risk of treatment failure and increased mortality in

neutropenic patients, therapeutic drug monitoring is justified in patients in whom therapy is failing or suspected risk factors for low blood levels (ie, poor gut function, drug interactions, and pediatric patients) or, in the case of voriconazole, suspected CNS toxicity, which is more frequent in patients with trough levels exceeding 5.5 μg/mL.[54] Similarly, posaconazole serum concentrations <0.7 μg/mL have been associated with an increased risk of breakthrough infection during prophylaxis, and trough or random levels approaching 1.5 μg/mL have been associated with an improved probability of treatment response in documented invasive aspergillosis.[54] Serum antimycotic concentrations may be more easily monitored in the future because assays, potentially performed at the point of care (patient bedside or clinic), become available, and correlations between concentration and efficacy or toxicity are more clearly established.[55]

SYSTEMIC MYCOSES

Candida Infection

CASE 78-3

Question 1: L.K., a 21-year-old, 68-inch (172.72 cm), 170-pound (77.11 kg), otherwise healthy male, was admitted to the hospital 16 days ago after a gunshot wound to the abdomen. He has undergone three exploratory laparotomies with repair and resection of damaged small intestine. He was placed on TPN to allow his bowel to rest and received stress doses of methylprednisolone since day 6 in the hospital. Three days ago, he exhibited a fever of 102.38 °F (39.1 °C) and chills; his blood pressure of 100/70 mm Hg had dropped more than 30 mm Hg (systolic). Vancomycin and meropenem were promptly begun after obtaining blood cultures. Despite 3 days of antibiotics, he remains febrile. His physical examination reveals a Hickman catheter in the right subclavian vein that is functioning normally; no inflammatory changes are evident at the exit site. A single erythematous nodule about 0.5 cm wide is noted near the left wrist. The funduscopic examination of both eyes is normal. A

chest radiograph is also normal. The white blood cell (WBC) count is currently 10,950 cells/μL, and renal function is normal.

What subjective and objective data in this case suggest a possible *Candida* infection?

EPIDEMIOLOGY

Although it is possible that L.K. might be infected with bacterial pathogens not susceptible to vancomycin and meropenem, the possibility of a candidal infection should be considered. *Candida* species are the most common nosocomial fungal pathogens. *Candida* species were responsible for 72.2% of mycoses in hospitalized cases, and *C. albicans* accounted for 55% of these cases in the Centers for Disease Control, National Nosocomial Infections Surveillance System. Attributable mortality associated with disseminated candidiasis from all species is 38% and it is ~12% for extremely low-birth-weight neonates.[56] These statistics may underestimate the true occurrence because systemic candidiasis is difficult to diagnose. To reinforce this point, the diagnosis of systemic candidal infection is made in 30% to 50% of neutropenic patients with hematologic malignancies at postmortem.[57] Therefore, the morbidity for systemic candidiasis may be even higher because of the limited ability to diagnose systemic disease.

CHARACTERISTICS

The diagnosis and monitoring of therapeutic outcomes for systemic candidal infection are difficult because the characteristics of systemic candidal infection are subtle. Salient clinical features include constitutional symptoms (eg, fever, chills, and hypotension) and evidence of end-organ dissemination, such as nodular erythematous skin lesions, endophthalmitis, liver abscess, and spleen abscess. In addition, 50% of patients or fewer will have a single positive *Candida* blood culture. The Mycoses Study Group uses a single positive culture from a sterile body site and hypotension (systolic blood pressure [SBP] <100 mm Hg or an SBP decrease >30 mm Hg) or abnormal temperature (<35.5 °C or >38.6 °C) on one occasion or

>37.8 °C on two separate occasions more than 4 hours apart), or inflammation at an infected site as diagnostic criteria.

RISK FACTORS

Risk factors for candidemia include central venous catheters, broad-spectrum antibiotic use, extensive surgical procedures, *Candida* colonization, TPN, pancreatitis, neutropenia or neutrophil dysfunction, and immunosuppression (eg, premature infants, burn patients, patients with mannose-binding lectin deficiency, and patients with AIDS).[58]

L.K. has chills, a temperature of 102.38 °F (39.1 °C), and is hypotensive. He is probably immunosuppressed as a result of multiple surgical procedures and receipt of corticosteroids. His Hickman catheter is a possible portal of entry, and his broad-spectrum antibiotic therapy with vancomycin and meropenem should be adequate for most bacterial pathogens. Because L.K. still has manifestations of an infection despite 3 days of antibiotics, additional diagnostic studies are warranted.

DIAGNOSTIC TESTS

Case 78-3, Question 2: What diagnostic tests could be ordered for L.K. to evaluate a possible fungal infection?

The diagnosis of fungal infection may be made with varying levels of certainty. Sometimes, the diagnosis is absolutely certain, such as the isolation of a pathogenic fungus from a clinical specimen in an immunocompromised patient. Such a finding is referred to as a definitive or microbiologically confirmed diagnosis. At other times, only a high probability of infection can be determined, that is, a presumptive diagnosis. To illustrate this, a patient with a chest radiograph showing nodular lesions and a high complement fixation (CF) antibody against *H. capsulatum* would have a presumptive diagnosis of histoplasmosis. This finding may be as certain a diagnosis as is possible without performing a more invasive

procedure to obtain lung tissue. In this event, a trial of drug therapy can be undertaken on the presumptive diagnosis alone. A diverse spectrum of tests is available for clinicians to diagnose and monitor therapeutic responses.

Direct examination

Direct examination of the specimen is often useful in diagnosing fungal infection. Traditionally, the specimen is treated with 10% KOH to digest the cells and debris, resulting in clear visualization of the hyphae or yeast. Treatment of cerebrospinal fluid (CSF) specimens with KOH is not necessary because this fluid is naturally clear. India ink can be added to CSF to increase contrast and outline the organisms. Calcofluor white, a fluorescent fabric brightener that binds to fungi and fluoresces brilliantly when viewed under the ultraviolet microscope, can also be used to assist in the recognition of fungal elements.

Histologic examination of biopsy specimens is an important tool for diagnosing and monitoring fungal infection, but identifying the exact fungus may be difficult. This is because only the tissue phase can be observed, and the fungal organisms in the specimen may be few. Because recognizing a fungus in hematoxylin-stained or eosin-stained sections may be difficult, a number of special stains have been developed.[58] Periodic acid–Schiff staining binds linked sugar groups in the fungal cell wall. This intense magenta staining makes visualization of the fungal form easier. Likewise, several silver precipitation stains (eg, Gomori methenamine silver) rely on the presence of a charged fungal surface to reduce oxidized silver to metallic silver. This process coats the fungus with a black layer, again outlining the form.[59] The mucicarmine stain imparts a deep red color to complex polysaccharides, such as mucin, which can stain the thick capsule of *C. neoformans*. Because no other yeast has a positive mucicarmine stain, the definitive diagnosis of cryptococcosis can be made.[60] The size of the organism, manner of budding, and the presence or absence of septae all assist in the diagnosis.

Monoclonal antibodies against many fungi are now available. Immunohistochemical procedures using these sera on biopsy specimens allow for the identification of a number of fungal pathogens.[60] Reagents for in situ oligonucleotide probe hybridization to detect fungi in tissue are being developed and will also be extremely helpful.[61]

Culture

The most definitive method for diagnosing or monitoring a fungal infection is using culture. Specimens should be inoculated onto several different types of fungal media, some of which contain antibiotics to inhibit bacterial overgrowth. Swab specimens have a very low yield, especially for hyphal fungi, and should be avoided in follow-up cultures. Yeast may grow rapidly and be isolated within 24 to 48 hours, but many fungi grow slowly, and 4 to 6 weeks of incubation may be necessary to isolate and identify the organism. After growth, yeasts are usually recognized by their patterns of metabolic activity on a variety of substrates, whereas mycelial organisms may produce characteristic spores and fruiting bodies that are used for identification. Occasionally, a mycelial organism will be slow in producing recognizable spores, and immunologic testing for a characteristic isoantigen may be used for identification. A peptide nucleic acid fluorescence in situ hybridization test more rapidly identifies *C. albicans* from blood-culture bottles.[62] It is unclear how cost-effective this test will be compared with traditional germ-tube testing.

Antigen detection

Fungi synthesize polysaccharides that cannot be broken down by human enzymatic systems. These polysaccharides can accumulate within the body and can be excreted in the urine. These fungal antigens can be detected by using antibodies that specifically recognize a particular species of fungus, thereby providing a diagnosis. The most commonly used antigen detection test is a latex agglutination test for cryptococcal antigen. This assay can be

performed on serum or CSF. Antigenemia is present in 80% to 100% of patients with culture-proved cryptococcal meningitis. This test can also be used to monitor patient response to therapy by determining the end point dilution for the positive reaction and following this end point over time when the patient is treated. If treatment is successful, the titer will decline.[63],[64]

Tests (quantitative polymerase chain reaction, enzyme-linked immunosorbent assay [ELISA], and latex agglutination) for other fungal antigens are also not established. Latex particle agglutination tests to detect candidal antigens are available, but their use has not been clearly demonstrated. Assays for detecting *H. capsulatum* antigen in serum and urine have been reported.[65] Antigen can be detected in the blood of 50% of patients and in the urine of 80% to 90% of patients with systemic histoplasmosis. Patients with blastomycosis and paracoccidioidomycosis, however, may also have positive cross-reactions. The ELISA for the detection of *Aspergillus* galactomannan antigen and *Candida* (1–3)-β-D-glucan has reported sensitivity (63%) and specificity (96%) of two consecutive (1–3)-β-D-glucan results >7 pg/mL, which is clinically useful. Using these tests can result in a shorter time to diagnosis and leads to a significantly shorter time of illness compared with other diagnostic tests. β-Glucan is most valuable for its negative predictive value.[66] Considering the presence of false-positives or false-negatives, it is unknown whether these assays will improve diagnostic capability for patients at a risk for these infections. False-positives may be caused by a myriad of products (IgG, albumin, cellulose filters, or gauze bandages) with variable outcomes associated with piperacillin/tazobactam. Increasing or decreasing values can be used to monitor clinical response to antifungal therapy.[62]

Antibody detection

The detection of antibody can be useful for some fungal diseases, but not for others. Serologic diagnosis of systemic candidiasis is complicated because most people have anti-*Candida* antibodies. A rising titer is not specific for infection and may indicate only

colonization. Furthermore, dissemination of *Candida* is most likely in people who are immunocompromised and, therefore, may not respond by producing antibody.[67] On the other hand, seropositivity can be demonstrated in more than 90% of patients with symptomatic histoplasmosis.[68] The most important serologic tests use the CF, immunodiffusion, and enzyme immunoassay (EIA) techniques. The appropriate evolution of serologic results requires an understanding of the sensitivity, specificity, and predictive value of each methodology. In general, serologic tests allow only a presumptive diagnosis of mycotic infections.

Although any of the aforementioned tests could be ordered for L.K., a direct examination of his blood and urine specimens along with an assessment of signs and symptoms of disseminated candidiasis is a reasonable first step in his evaluation. A blood specimen from L.K. should also be cultured on different fungal media. Because a candidal infection is suspected, the culture could isolate *Candida* within 24 to 48 hours. Cultures and histopathologic examination of a biopsy specimen of skin lesions are often helpful not only in confirming a diagnosis of disseminated candidal infection but also in monitoring response to therapy. The other fungal tests previously described need not be ordered immediately and should await the results from the direct examination and culture.

NECESSITY OF TREATMENT

Case 78-3, Question 3: The clinical laboratory reports that a single blood culture obtained 2 days ago is growing *Candida* species. Why is therapy necessary in L.K. with only a single positive blood culture?

Case–control studies of candidemia report an 85.6% mortality rate in untreated patients compared with a 41.8% mortality rate in patients who received early treatment. Isolation of *Candida* from a patient's bloodstream requires the initiation of immediate antifungal therapy. Delays in therapy are associated with a significant increase in mortality. In fact, delaying therapy 24 hours from the time a blood

culture is positive or failure to follow the Infectious Disease Society of America (IDSA) treatment guidelines increases mortality by nearly 50%.[69–71] Elimination of risk factors may improve the clinical outcome of candidemia, and the removal of central venous catheters reduces morbidity and mortality.[72],[73] Although discontinuation of a centrally inserted catheter may complicate drug administration, it still should be removed. L.K.'s other risk factors (eg, broad-spectrum antibacterials) are perhaps of even greater importance.

TREATMENT OPTIONS AND COMBINATION THERAPY

CASE 78-3, QUESTION 4: What therapeutic options are available to treat candidemia? Which option would be best for L.K.?

Therapeutic options are individualized and based on the competence of a patient's host defenses. In immunocompetent patients, AmB formulations, an echinocandin, or a triazole decreases morbidity and mortality associated with this disease.[74–78] Echinocandins have been demonstrated as effective as AmB formulations in neutropenic and non-neutropenic patients; however, AmB clears the bloodstream more rapidly.[79],[80] In the largest, well-controlled comparative trial, 206 non-neutropenic patients were randomly assigned to AmB 0.5 to 0.6 mg/kg/day or fluconazole 400 mg/day for 14 days. Mortality was <9% in both the groups with no significant difference in successful outcomes (AmB, 80%; fluconazole, 72%). Less toxicity was noted in the fluconazole group, however.[75] Therefore, fluconazole 400 mg/day is as effective as AmB for non-neutropenic patients infected with susceptible *Candida*. Candidemic (or other mycotic infections discussed in this chapter) patients who are clinically stable and have no evidence of deep-seated infection should be initiated on a triazole or an echinocandin for at least 14 days. Patients who cannot be treated with an echinocandin or an azole can be treated with AmB 0.5 to 1.0 mg/kg/day or 3 to 5 mg/kg/day of a lipid formulation of AmB. Alternatively, a comparison of micafungin (100 or 150 mg) with

caspofungin revealed no difference with micafungin 100 mg and caspofungin after 10 days of therapy. However, micafungin 150 mg trended toward poorer responses.[81]

High-dose fluconazole (12 mg/kg/day) alone or in combination with AmB for a minimum of 3 days, followed by step-down therapy to fluconazole, was evaluated. Outcomes were not different between treatment groups and consistent with the previously reported success rates. Notably, the fluconazole treatment group had higher Acute Physiology and Chronic Health Evaluation (APACHE II) scores, making the evaluation of the comparison difficult.[79] In contrast, in another clinical trial, the combination of AmB and flucytosine was suggested to be more effective than single-agent therapy.[82,83] An AmB-containing regimen may be more effective in patients with APACHE II scores between 10 and 22.[79]

L.K. could be treated with an echinocandin, with the total duration based on clinical response and resolution of positive cultures (see Case 78-3, Question 6). Therapy typically should be continued for 14 days post–last positive blood culture. Some clinicians check cultures daily to assess this end point. Efficacy should be monitored using patient-specific signs and symptoms of candidemia. Combination therapy can be considered in those patients who are not responding clinically. More importantly, a complete examination for focal sites of infection (septic thrombi or intra-abdominal abscess) should take place.

CASE 78-3, QUESTION 5: This fungal species has now been identified as *C. non-albicans*. How does this affect the therapeutic options for L.K.?

Historically, the isolation of a non-albicans *Candida* from blood has resulted in a therapeutic dilemma caused by common in vitro resistance, which has been associated with poor clinical outcomes in animal models and uncontrolled case reports. Intrinsic resistance (ie, *Candida lusitaniae* to AmB, *C. parapsilosis* to echinocandins, and *Candida krusei* to fluconazole) or acquired resistance (*C. tropicalis* or *glabrata* against fluconazole) has been reported.[76,82,83] Acquired

in vitro fluconazole drug resistance is probably associated with altered fungal cell membrane permeability, antifungal efflux pumps, and changes in CYP450 enzymes. In observational studies, fluconazole resistance in vitro has been 9%.[76],[82],[83] A large, multicenter study of 232 non-neutropenic patients was unable, however, to demonstrate a relationship between yeast MIC and patient outcome.[76] An inability to demonstrate a relationship is probably a result of a limited understanding or inadequate management of risk factors for infection. For example, the removal of a colonized IV catheter is probably a more important predictor of outcome than the MIC of the isolated yeast. A disturbing increase in acquired *C. glabrata* resistance to the echinocandins via an *FKS* gene, first reported in 2008, should be suspected in echinocandin treatment failures.[27],[84]

Therefore, the true rate of acquired clinical resistance to azoles and ultimate failure is unknown. Vigilant monitoring and aggressive therapy of infections caused by *Candida non-albicans* are recommended. In patients in whom susceptibilities are available, fluconazole should be avoided when the MIC is >16 µg/mL.

AMPHOTERICIN FORMULATIONS

Dosing

Case 78-3, Question 6: How should amphotericin B formulation be dosed and administered to L.K.?

The AmB formulation dose and duration of therapy should be individualized based on the severity of infection and immunocompetence of the patient. Once the patient is stable, therapy should be changed to one of the applicable regimens discussed previously. The dose of AmB formulations should be based on lean body mass. Owing to the difficulty in measuring lean body mass, many clinicians, however, use ideal body weight. Tissues that contain large numbers of macrophages sequester significant amounts of AmB (liver, 17.5%–40.3%; spleen, 0.7%–

15.6%; kidney, 0.6%–4.1%; and lung, 0.4%–13%), but it does not distribute well into adipose tissue (>1.0%).[77],[78] In fact, AmB formulations bound to cholesterol have been shown to bind to clathrin-coated pits (low-density lipoprotein receptors or receptors of endocytosis) on cells, facilitating intracellular incorporation and possibly reducing renal toxicity.[85] Because L.K. is 68 inches (172.72 cm) tall and not obese, his ideal body weight should be about 154.32 pounds (70 kg). Therefore, generic AmB 35 mg/day (0.5 mg/kg) should be initiated because L.K. is not clinically stable and may require increased doses. Half of the full dose should be given on the first day of therapy and the full dose given on subsequent days. In more seriously ill patients, the full dose of generic AmB can be initiated immediately. Although the optimal dosing regimen to initiate generic AmB is not well established, most clinicians gradually titrate the dose upward to minimize infusion-related reactions. Peak AmB serum concentrations achieved after parenteral administration are a function of dose, frequency of dosing, and the rate of infusion. When the AmB total dose is <50 mg, the serum concentration is directly proportional to the dose; doses >50 mg are associated with a plateau in serum concentrations. After administration, AmB undergoes biphasic elimination: Peak serum concentrations drop rapidly (initial $t_{1/2}$, 24–48 hours), but low concentrations (0.5–1.0 μg/mL) are detectable for up to 2 weeks (terminal $t_{1/2}$, 15 days).[86] The long terminal elimination half-life has been used as a justification for the common practice of less frequent AmB dosing, in which twice the daily dose is given every other day. Every-other-day regimens have not been carefully evaluated but are rationalized based on the potential for reduced nephrotoxicity. Administration of generic AmB 0.5 mg/kg/day or 1.0 mg/kg every other day results in trough AmB concentrations with sufficient postdose antifungal effects that inhibit the common pathogenic fungi.[87] Once L.K.'s clinical status has improved, the potential for renal toxicity could outweigh the concerns of potential reduced efficacy, and implementation of AmB every-other-day therapy should be considered.

Infusion reactions

Case 78-3, Question 7: L.K. has no problems except for fevers and shaking chills that occur during his 6- to 8-hour AmB infusion for the past 3 days. He has been receiving acetaminophen 650 mg 30 minutes before AmB infusion, but he has refused today's AmB dose. What measures can be taken to minimize these infusion-related reactions?

Adverse reactions, which are common with AmB formulation administration, are best classified as infusion-related, dose-related, or idiosyncratic reactions. Infusion-related reactions include an acute symptom complex of fever, chills, nausea, vomiting, headache, hypotension, and thrombophlebitis. Dose-related reactions also can be acute (eg, cardiac arrhythmias) or chronic (eg, renal dysfunction with secondary electrolyte imbalances and anemia). Premedication to prevent AmB formulation, infusion-related reactions, and a test dose of AmB formulations are not needed for L.K. Most practices of premedicating are performed out of ritual rather than predicated on a scientific study.[88] Test dosing with 1 mg before the first dose is not currently used because of the immeasurably low incidence of anaphylactoid reactions. Until clinical trials clarify the risk–benefit ratio of premedications, concomitant therapy should be restricted to acetaminophen for fever or headache and heparin to prevent thrombophlebitis when possible.

Many infusion-related reactions are mediated by AmB-induced cytokine (interleukin-1β, tumor necrosis factor, and prostaglandin E_2) expression by mononuclear cells.[89,90] Hydrocortisone is extremely effective in suppressing cytokine expression,[89] and it also blunts the fever and chills associated with AmB formulations.[91] Hydrocortisone, however, does not reduce the frequency of chronic dose-related toxicity such as renal insufficiency, and corticosteroid-induced immunosuppression could decrease AmB fungicidal activity.[92] Nonsteroidal anti-inflammatory drugs (NSAIDs) also prevent fever, most likely by the suppression of prostaglandin E_2 expression.[93] NSAIDs, however, cannot be recommended for routine use because

of their potential for additive nephrotoxicity when used with AmB formulations.

The mild-to-moderate elevations in temperature and the other infusion-related symptoms usually subside when the infusion is completed, and tolerance to these effects develops over 3 to 5 days. L.K. initially should be counseled that these reactions will abate over the next few days without intervention. If assessment of the reactions suggests the need for more aggressive premedication, a short course of hydrocortisone 0.7 mg/kg prior to AmB or added to the infusion bag should be initiated.[91] Meperidine 25 to 50 mg by rapid IV infusion reduces AmB-induced rigors and can be repeated every 15 minutes as required while monitoring for signs and symptoms of opiate toxicity. Administration of an average meperidine dose of 45 mg has been found to resolve chills three times faster than placebo.[94]

Fast generic AmB infusion rates (> normal 4–6 hours) are associated with the earlier onset of infusion-related reactions, but not with more severe infusion reactions.[95],[96] Many patients prefer rapid infusions (1–2 hours) because the infusion-related reactions abate quickly on the completion of the AmB infusion. Electrocardiographic evaluations of 1-hour infusions indicate that this rate of polyene infusion is safe at currently recommended doses in patients without renal or heart disease. Rapid infusions are not safe in all patients, however, because cardiac arrhythmias appear to be dose- and infusion rate–related. If infused too rapidly, high serum concentrations of AmB can precipitate severe cardiac adverse events. Arrhythmias have been reported most often in patients who are anuric or who have previous cardiac disease.[97] Continuous infusion is not recommended based on the pharmacodynamics of this agent and the concentration dependence of activity.

Nephrotoxicity

Case 78-3, Question 8: On day 4 of therapy with AmB, L.K.'s serum creatinine (SCr) and blood urea nitrogen (BUN) are 2.3 mg/dL (SI units, 203.32

μmol/L) and 42 mg/dL (SI units, 14.99 mmol/L), respectively. How could AmB exacerbate L.K.'s renal dysfunction and how could it be prevented from worsening?

Renal dysfunction is the adverse event that most often limits treatment with AmB formulations. The renal toxicity results from AmB-mediated damage to renal tubules, which causes electrolyte wasting and disrupts the tubuloglomerular feedback mechanism. The clinical manifestations of AmB-induced renal damage include azotemia, renal tubular acidosis, hypokalemia, and hypomagnesemia.[88] The renal insult along with infusion-related reactions appears less severe in patients with higher serum cholesterol. This may be associated with the clathrin binding discussed earlier. Generally, AmB-related renal toxicity is reversible within 2 weeks after therapy has been discontinued. Administration of normal saline (250 mL) immediately before AmB administration reduces the risk for AmB-induced nephrotoxicity[98] and should be initiated before L.K.'s next dose. AmB formulations should not be admixed with normal saline, however, because sodium causes AmB to precipitate into an inactive particulate in IV admixture formulations.[99] Other nephrotoxins should be avoided (especially diuretics), and patients with already-compromised renal function should be closely monitored and alternate therapy should be considered.[99] Hypokalemia and hypomagnesemia should also be monitored closely. These measures to prevent further renal deterioration should be implemented, and the AmB therapy continued cautiously in this patient with systemic candidiasis. Anemia, associated with decreased renal production of erythropoietin, should resolve after AmB is discontinued and need not be treated.[100]

Case 78-3, Question 9: L.K. has exhibited significant renal dysfunction resulting from acute tubular necrosis. How should his dose of systemic antifungal drugs be altered?

Renal elimination of the antimycotics varies tremendously. For systemically administered AmB, only 5% to 10% of unchanged drug is eliminated in urine and bile during the first 24 hours,[88] and no evidence indicates that it is metabolized to a significant extent. Therefore, no substantial dosage adjustment is required for patients with chronic renal or hepatic failure. Although many clinicians will withhold AmB doses if acute renal dysfunction develops during therapy, concerns of drug-induced nephrotoxicity in L.K. must be balanced against the high likelihood of mortality in untreated patients with deep-seated infections.[55],[56] Alternative systemic antifungal therapy (ie, azoles or echinocandins) that is less nephrotoxic should also be considered. Dosing recommendations for echinocandins are unchanged in renal dysfunction or liver dysfunction, except for caspofungin. For patients with moderate hepatic insufficiency (Child–Turcotte–Pugh score 7–9), a change in the maintenance dose of caspofungin to 35 mg/day is recommended, even though the higher exposures expected with the standard dose are generally well tolerated. No data are available for caspofungin used in severe hepatic impairment, and a further dosage reduction should be considered.

Ketoconazole and itraconazole undergo first-pass metabolism and have a biphasic dose-dependent elimination.[45],[46] These agents are extensively metabolized and excreted in the bile; small amounts of unchanged drug are excreted in the urine; therefore, no need exists to adjust dosages in patients with renal dysfunction or in patients undergoing dialysis.[101] Voriconazole is extensively metabolized by cytochrome P450 2C19 and to a lesser extent CYP3A4 to inactive metabolites excreted in the urine. However, the IV formulations of voriconazole and posaconazole are solubilized in sulfobutylether-β-cyclodextrin, which is eliminated via the kidneys. Accumulation of the cyclodextrin vehicle is associated with a theoretical potential for renal toxicity not reported to date in patients including those with renal impairment.[102],[103] Therefore, oral therapy (or possibly isavuconazole) may be preferred in patients who require a broad-spectrum triazole but have impaired renal function. Fluconazole, unlike ketoconazole and itraconazole, is not extensively metabolized. More than 90% of a

fluconazole dose is excreted in urine, of which about 80% is measured as unchanged drug and about 20% as metabolites.[104] Because fluconazole is excreted primarily unchanged in the urine, dosages should be adjusted in patients with renal insufficiency (see **Table 78-5**).[23,24,45–48,88,101–111] Fluconazole or voriconazole may be reasonable alternatives in L.K., but the dosage must be adjusted for renal function based on published nomograms.[105]

CASE 78-3, QUESTION 10: What is the role of an AmB formulated with a lipid?

Lipid formulations of AmB have been approved by the FDA for patients who are unable to tolerate generic AmB (**Table 78-6**). In addition, the admixture of AmB in 10% or 20% lipid emulsion has been used for treating systemic mycotic infections. The lipid carriers differ tremendously for each of the amphotericin formulations. The liposomal formulation is a spherical carrier that contains AmB on both the inside and outside of the vesicle. Imagine the lipid complex as a snowflake shape and the colloidal dispersion shaped like a Frisbee with AmB bound to the structure. The differences in structure appear to have no effect on therapeutic outcome but exhibit markedly different pharmacokinetics and rates of AmB release in vivo, which may account for difference in the rates of adverse effects observed with each formulation.[112] AmB admixture with a lipid emulsion cannot be recommended until a stable formulation can be established.[113] Yet, similar in concept, some clinicians administer AmB formulations with breakfast (high-cholesterol meals) to simulate or enhance “lipid” coadministration, macrophage clathrin pit binding, and subsequent decreases in toxicity.

Table 78-6
Amphotericin B Formulations

Category	Amphotericin B (Fungizone)	Amphotericin B Lipid Complex (Abelcet®)	Amphotericin B Colloidal Dispersion (Amphotec®)	Liposomal Amphotericin B (AmBisome®)		Amphotericin B in Lipid Emulsion
FDA-approved indication	Life-threatening fungal infections Visceral leishmaniasis	Refractory or intolerant to AmB	Invasive Aspergillosis in patients refractory or intolerant to AmB	Empirical therapy in neutropenic FUO Refractory or intolerant to AmB Visceral leishmaniasis		NA

AmB, amphotericin B; AUC, area under the curve; DMPC, dimyristoylphosphatidylcholine; DMPG, dimyristoylphosphatidylglycerol; DSPG, distearolyphosphatidylglycerol; EPC, egg phosphatidylcholine; FDA, U.S. Food and Drug Administration; FUO, fever of unknown origin; NA, not applicable.

[a]Molar ratio of each component, respectively.

[b]No benefit for longer infusions.

[c]Doses >10 mg/kg have no benefit.

Limited data on AmB formulation comparisons are available to assist in the management of this case. A single, large controlled trial has evaluated AmB lipid complex for the treatment of disseminated candidiasis. Generic AmB 0.6 to 1.0 mg/kg/day for 14 days was slightly, but not significantly, superior to the lipid complex formulation at 5 mg/kg/day for mycologic efficacy (68% vs 63%) or survival.[114] Renal dysfunction defined as a doubling in SCr, however, was 47% with AmB and 28% with this lipid formulation. Because of the significant cost, some health care facilities reserve lipid formulations for patients who have preexisting renal dysfunction or those who have severe adverse reactions to generic AmB. However, most centers use lipid formulations as their formulary polyene owing to patient acceptance and cost of AmB-associated renal dysfunction. Indications for the lipid formulations are further reviewed in the discussion of sections on aspergillosis, histoplasmosis, and cryptococcosis.

ANTIMYCOTIC PROPHYLAXIS

CASE 78-3, QUESTION 11: What measures could have been undertaken to prevent invasive fungal infections in L.K.?

In 2014, the National Institutes of Allergy and Infectious Diseases (NIAID)/Mycoses Study Group completed a randomized, double-blind, placebo-controlled trial of caspofungin prophylaxis followed by preemptive therapy for invasive candidiasis initiated on the basis of an antigen diagnostic test (β-D-glucan) among high-risk patients in the intensive care unit (ICU) setting.[115] The study used a validated risk prediction score for invasive candidiasis that identified 18% of subjects admitted to the ICU with a predicted invasive candidiasis incidence rate of >10%. Caspofungin prophylaxis was not associated with a reduction in the incidence of proven or probable invasive candidiasis or patient mortality. Therefore, prophylaxis among non-neutropenic patients at this time should be restricted to patient populations with proven benefit: post-GI perforation, severe

pancreatitis, liver/pancreas or small bowel transplant recipients, and extreme low-birth-weight neonates.[57]

Selective GI decontamination or systemic antimycotic pharmacotherapy can be used in high-risk, immunocompromised, or surgical patients to prevent the development of fungal infections and could have been used for L.K. In critically ill surgical patients, the risk of invasive infection, but not mortality, may be reduced by more than 50% with fluconazole prophylaxis.[116] Alternatively, a nonabsorbable antifungal such as AmB or nystatin is a possible option. Oral AmB decreases systemic candidal infections threefold to fivefold in high-risk patients.[117] Yet the problems of unreliable antifungal stool concentrations,[118] decreasing azole cost associated with the availability of generics, and poor compliance have led to preferential azole use. Azoles are also more effective in preventing oral pharyngeal candidiasis than placebo.[119],[120] At the present time, no well-designed studies have compared azoles with polyene antifungals (eg, AmB) for the prevention of oropharyngeal or systemic candidiasis.

Prophylaxis could be initiated and continued until L.K. is no longer immunocompromised. If L.K. is discharged from the hospital and treated as an outpatient, a systemic azole (imidazole or triazole) administered once daily is preferable to a polyene to improve adherence. To reemphasize, however, systemic therapy increases the risk of resistance, adverse effects, drug interactions, and potentially cost (see **Table 78-4**). Therapeutic drug monitoring may be necessary in these patients.

Candiduria

TREATMENT

CASE 78-4

QUESTION 1: M.Y., a 24-year-old male, has been hospitalized in the surgical ICU with multiple traumatic injuries resulting from a motor vehicle accident. Shortly after admission, he underwent an exploratory laparotomy for a ruptured spleen

and lacerated liver. He subsequently suffered from respiratory and renal failure. M.Y. is currently intubated and on mechanical ventilation. Since admission, he has been nutritionally supported with central hyperalimentation and has been receiving broad-spectrum antibiotics (gentamicin, ampicillin, and metronidazole). A Foley catheter is in place. Two recent urinalyses (UAs) show budding yeast, and cultures were positive for >100,000 colony-forming units of *C. albicans*. M.Y. is currently afebrile, his funduscopic examination is normal, and no macronodular skin lesions are present. The WBC count is 8900 cells/μL (SI units, WBC count, 8.9×10^9/L), and three sets of blood cultures drawn during the past 2 days are negative.

How should M.Y.'s candiduria be treated?

It is difficult to differentiate among cystitis, urethritis, or systemic infection in the presence of funguria. Similarly, it is difficult to differentiate colonization from infection because candiduric patients are usually asymptomatic. Funguria cannot be used to determine the location or severity of invasion. Signs and symptoms of systemic disease should be monitored diligently until a diagnosis of colonization, cystitis, or urethritis is confirmed and the risk of dissemination is excluded.

Eradication of fungi in the urine (specifically *C. albicans*) should begin with the removal of the indwelling urinary catheter and alleviation of risk factors for fungal disease. If catheter removal does not clear the urine within 48 hours, pharmacotherapy should be considered. If M.Y. is scheduled for a genitourinary procedure, he should receive systemic therapy because the rate of candidemia after surgery is high (10.8%) in candiduric patients. In addition, any patient at a high risk for dissemination into the blood should be considered for treatment (eg, patients with immunosuppression).[121]

Bladder irrigation with AmB has been used in the past at concentrations of 150 μg/mL, however, has limited clinical utility, and is not recommended by the Infectious Diseases Society of America.[122] In two comparative studies, bladder irrigation for 5 days with AmB 50 μg/mL was superior to fluconazole 100 mg/day as measured by microbiologic cure rates. Clinical cure rates at 2 to 4 weeks were equal—however, mortality rates were higher in the AmB-treated groups. It was suggested that AmB failures may have

been associated with the dissemination of yeast from the urinary tract.[123],[124] Systemic antifungal therapy with flucytosine 100 to 150 mg/kg/day for 7 days[125] and azoles (fluconazole 0.6–1.4 mg/kg/day for 7 days)[126],[127] also has been used in noncomparative or nonrandomized studies. Newer triazoles (voriconazole, posaconazole, and isavuconazole) or echinocandins are not recommended for the treatment of candiduria owing to their low concentrations in urine, even though some case series have suggested that clearance of positive cultures is possible on echinocandin therapy.[128]

Blastomycosis

ETIOLOGY

CASE 78-5

QUESTION 1: C.P., a 17-year-old female from Arkansas, is admitted to the hospital with a chronic pneumonia that has not responded to antibiotics. Three months ago, she began to exhibit a chronic cough that eventually became productive of purulent sputum, which was occasionally streaked with blood. Two months ago, she began to exhibit "boils" on her lower extremities and back, which drained spontaneously. She was hospitalized at another hospital but failed to respond to amoxicillin and clarithromycin. C.P. denies fever, chills, or night sweats but has lost 11 pounds (4.99 kg). Her temperature is 100.76 °F (38.2 °C). A 2-cm^2 subcutaneous, fluctuant, tender mass is seen over the right mandible and a second fluctuant mass about 4 cm wide on the lower back. In addition, several 0.5- to 1-cm^2 ulcers with heaped-up, hyperkeratotic margins are noted on the lower extremities (**Fig. 78-2**). Rales are heard at the right lung base. C.P.'s leukocyte count is slightly elevated at 13,500 cells/μL (SI units, WBC count, 13.5 × 10^9/L). A chest radiograph shows a mass-like infiltrate in the right mid-lung field (**Fig. 78-3**). A wet preparation of ulcer scrapings and material aspirated from a subcutaneous abscess reveal numerous broad-based, budding yeast forms with refractile cell walls and multiple nuclei typical of *B. dermatitidis*.

Cultures of sputum, skin scrapings, and abscess material eventually confirmed the diagnosis.

What was the likely portal of entry for C.P.'s disseminated blastomycosis? Why should it be treated?

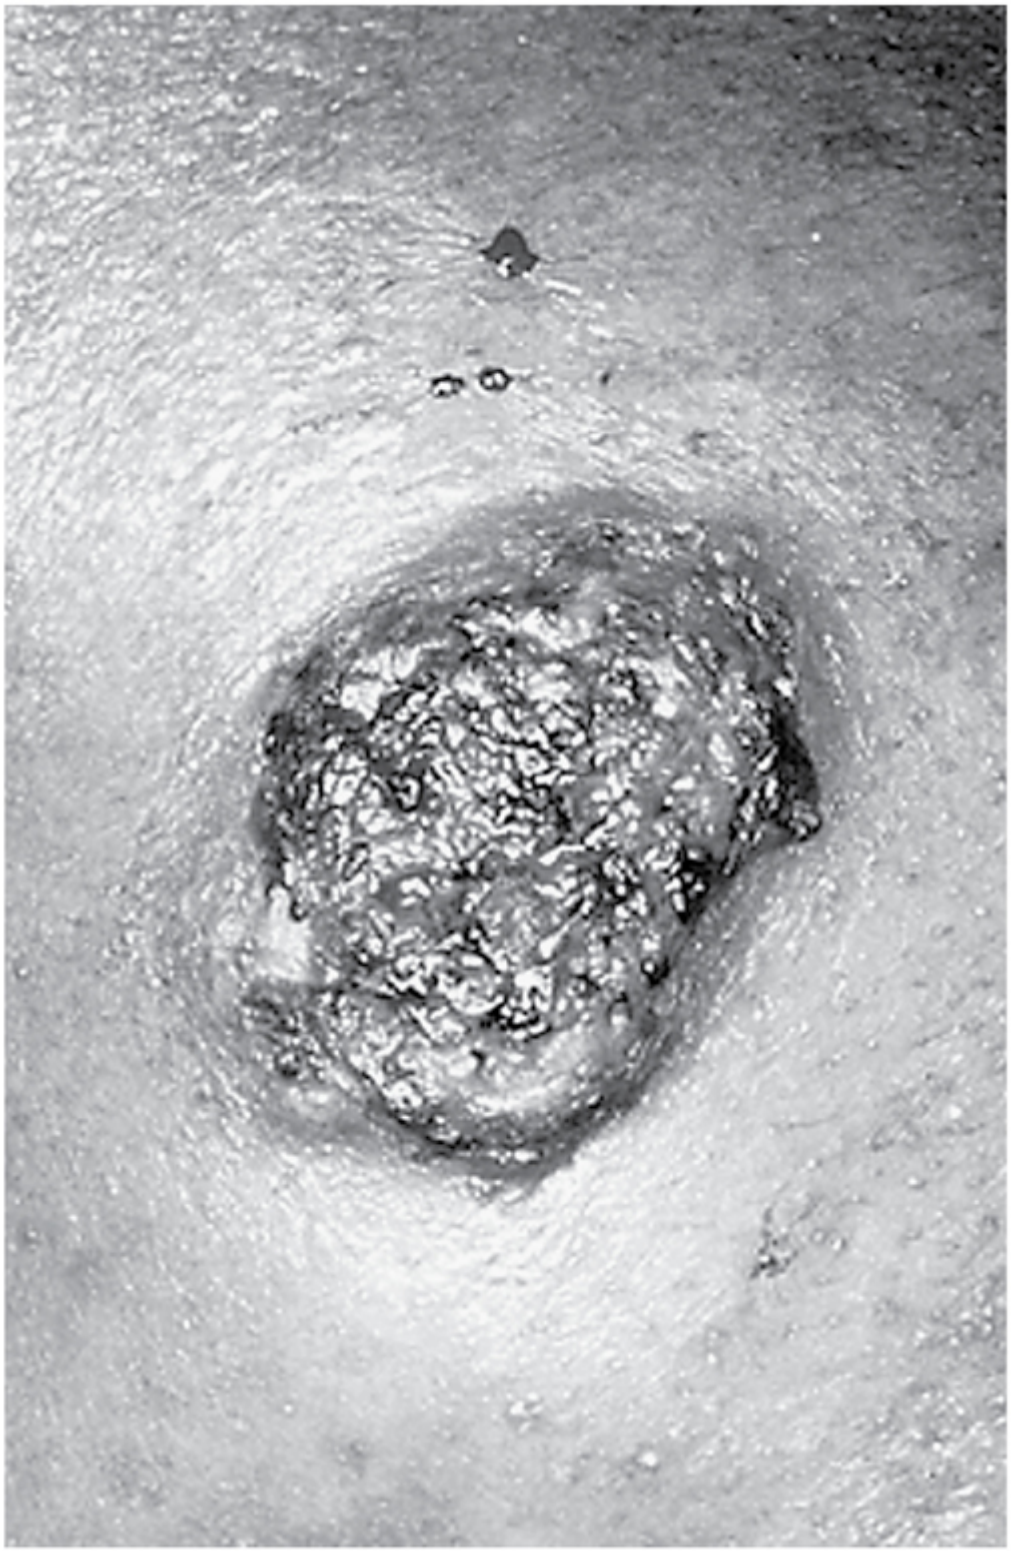

Figure 78-2 Disseminated Blastomyces dermatitidis skin ulcers.

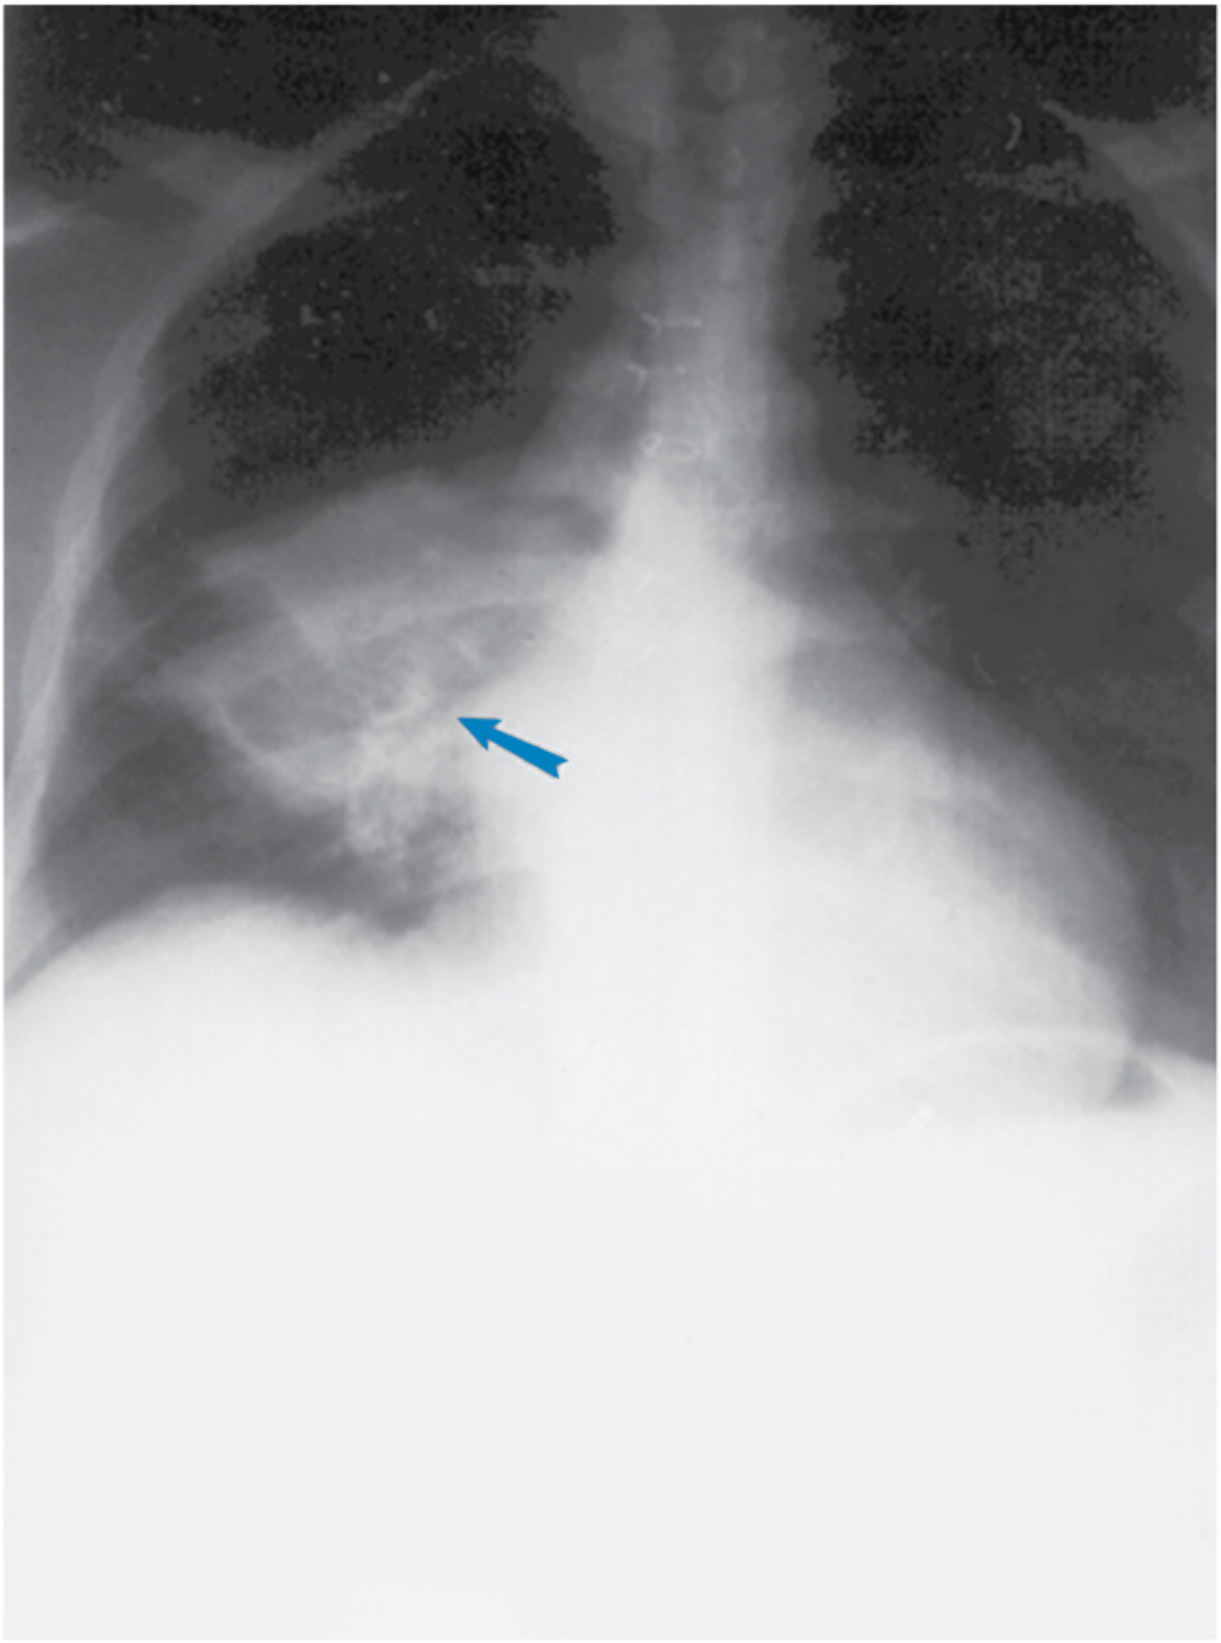

Figure 78-3 Chest radiograph of pulmonary Blastomyces dermatitidis. Arrow marks abnormality.

Typical of the other endemic mycoses, the primary portal of entry for *B. dermatitidis* is the lungs. A pulmonary origin for C.P.'s infection is supported by her history of cough with purulent, blood-streaked sputum, followed a month later with cutaneous lesions on her legs and back. An acute pulmonary infection is most often asymptomatic and, when symptomatic, usually requires only observation. Chronic pulmonary or extrapulmonary blastomycosis will develop in an unknown number of these patients. C.P.'s rales at the base of her right lung and persistent pneumonia unresponsive to antibacterials suggest a chronic pulmonary infection and a need for treatment. Chronic pulmonary disease often presents with radiographic studies often mistaken for tuberculosis or cancer; the mass-like infiltrate in her right lung on chest radiograph also is consistent with chronic pulmonary disease. Extrapulmonary infections can involve the skin (verrucous or ulcerative lesions), bone, genitourinary system (prostatitis and epididymo-orchitis), or CNS (meningitis or brain abscess). If untreated, these chronic pulmonary or extrapulmonary infections are fatal in at least 21% of patients.[129] Because C.P. presents with pulmonary and cutaneous evidence of blastomycosis, she should be treated.

TREATMENT

Case 78-5, Question 2: What specific therapy should be initiated for C.P.?

Historically, AmB formulations were considered the treatment of choice for blastomycosis, and total doses of more than 2 g were associated with 97% cure rates, low relapse rates, but also, however, substantial associated toxicity.[129] Ketoconazole and itraconazole are safe, effective alternatives to AmB in patients with non–life-threatening, non-CNS infections. The NIAID–Mycoses Study Group[130] confirmed the effectiveness of azoles for the

treatment of chronic pulmonary and extrapulmonary disease associated with blastomycosis and histoplasmosis. In uncontrolled evaluations of chronic pulmonary and extrapulmonary infections (excluding life-threatening or CNS), ketoconazole at dosages of 400 to 800 mg/day resulted in cure rates of about 89%, failure rates of about 6%, and relapse rates of about 5%.[130] In similar studies, itraconazole capsules of 200 to 400 mg/day for a median of 6.2 months resulted in cure rates of 88% to 95%.[131] Fluconazole was ineffective at dosages <400 mg/day. Higher dosages (400–800 mg/day), however, are as effective as ketoconazole in non–life-threatening diseases.[132] Although these trials are neither comparative nor controlled, itraconazole is less toxic than ketoconazole and with the best benefit (efficacy) to risk (toxicity) ratio.

C.P. has mild-to-moderate disease and can be treated with an initial itraconazole dosage of 200 mg/day. If no clinical improvement is seen within 2 weeks or if the disease progresses, the dosage of itraconazole can be titrated upward in 100-mg increments to a maximal dosage of 400 mg/day. Treatment should be continued for at least 6 months. If C.P. experiences severe or meningeal disease, itraconazole should be discontinued and AmB or a lipid-based AmB product should be initiated. C.P. should be followed up for 12 months owing to the risk of relapse. Unlike histoplasmosis, skin test and serologic testing are not sufficiently sensitive to diagnose blastomycosis or evaluate the effectiveness of treatment.[130,133] Rather, patients should be evaluated closely for resolution of symptoms (constitutional and pulmonary), negative microbiologic samples, and improvement in radiographic studies.

ANTIFUNGALS IN PREGNANCY

Case 78-5, Question 3: C.P. reports she has not menstruated in 3 months, and a urine pregnancy test is positive. How does this information change the therapeutic options for her?

Data on the safety of antimycotics for treating patients who are pregnant or lactating are limited but are comprehensively reviewed according to FDA categories of the teratogenic risks of drugs (see Chapter 49, Obstetric Drug Therapy).[134],[135] The systemic azoles are categorized with risk factor C. A recent Danish registration study did not find evidence of birth defects in females who took itraconazole during their first trimester.[136],[137] However, the majority of females analyzed in this registry received low cumulative doses of triazoles for thrush. However, these agents should be avoided in pregnant or lactating females who are breast-feeding because of their potential teratogenicity and endocrine toxicity in the fetus or newborn. As with the azoles, griseofulvin and flucytosine have been classified with risk factor C. These agents should not be used in C.P. because the risk clearly outweighs the therapeutic benefit. Few or no data exist on the secretion of these agents in breast milk. Therefore, breast-feeding should be discouraged in females receiving these antifungal agents.

AmB and terbinafine are classified as risk factor B. Therapeutic agents in this category have no fetal risk based on animal studies, or when risk has been found in animals, controlled human studies have not confirmed the results. There are limited data regarding the use of terbinafine in pregnancy. Consequently, clinicians should avoid terbinafine use in pregnancy until published data support a B classification. Furthermore, considerable clinical experience with AmB formulations in pregnant females has documented successful treatment of systemic mycoses with no excess toxicity to either the mother or the fetus. Thus, AmB formulations have been the mainstay of antifungal therapy in pregnancy.

Histoplasmosis

TREATMENT

CASE 78-6

QUESTION 1: J.N., a 47-year-old male with severe rheumatoid arthritis, has been maintained on daily prednisone for the past 6 years; his current dosage is

20 mg/day. For the past 4 weeks, he has experienced daily fevers to 101.12 °F (38.4 °C), drenching night sweats, anorexia, and an 18.08-pound (8.2-kg) weight loss. His prednisone dosage was increased to 40 mg/day with little clinical effect. On admission to the hospital, J.N. appears chronically ill and has many of the stigmata of chronic steroid therapy. His temperature is 100.04 °F (37.8 °C) with an associated rapid heart rate of 105 beats/minute. A shallow mouth ulcer is present on the hard palate. The liver is enlarged to a total span of 18 cm, and the spleen is palpable 3 cm below the left costal margin. Stool is positive for occult blood. A chest radiograph shows bilateral interstitial infiltrates (**Fig. 78-4A**). He is pancytopenic, with the following laboratory results:

Hematocrit, 29% (normal, 39%–45% SI units, 0.29)
WBC count, 3500 cells/μL (normal, 4000–11,000 cells/μL) (SI units, 3.5×10^9/L)
Platelet count, 78,000 cells/μL (normal, 130–400,000 cells/μL)
UA, 8 to 10 WBC/high-power field
SCr, 1.9 mg/dL (SI units, 167.96 μmol/L)
BUN, 42 mg/dL (SI units, 14.99 mmol/L urea)

The bilirubin is normal, but the aminotransferases are elevated to about 1.5 times normal, and serum lactate dehydrogenase is 10 times greater than normal. A bone marrow aspirate and biopsy of the mouth ulcer reveal multiple, small intracellular yeast forms compatible with *H. capsulatum* in macrophages and polymorphonuclear leukocytes (**Fig. 78-4B**). Cultures of blood and urine, bone marrow aspirate, and mouth ulcer biopsy grew *H. capsulatum*.

What is the optimal antifungal therapy in this case of systemic *H. capsulatum*? What clinical parameters should be monitored to assess the efficacy and toxicity of J.N.'s therapy?

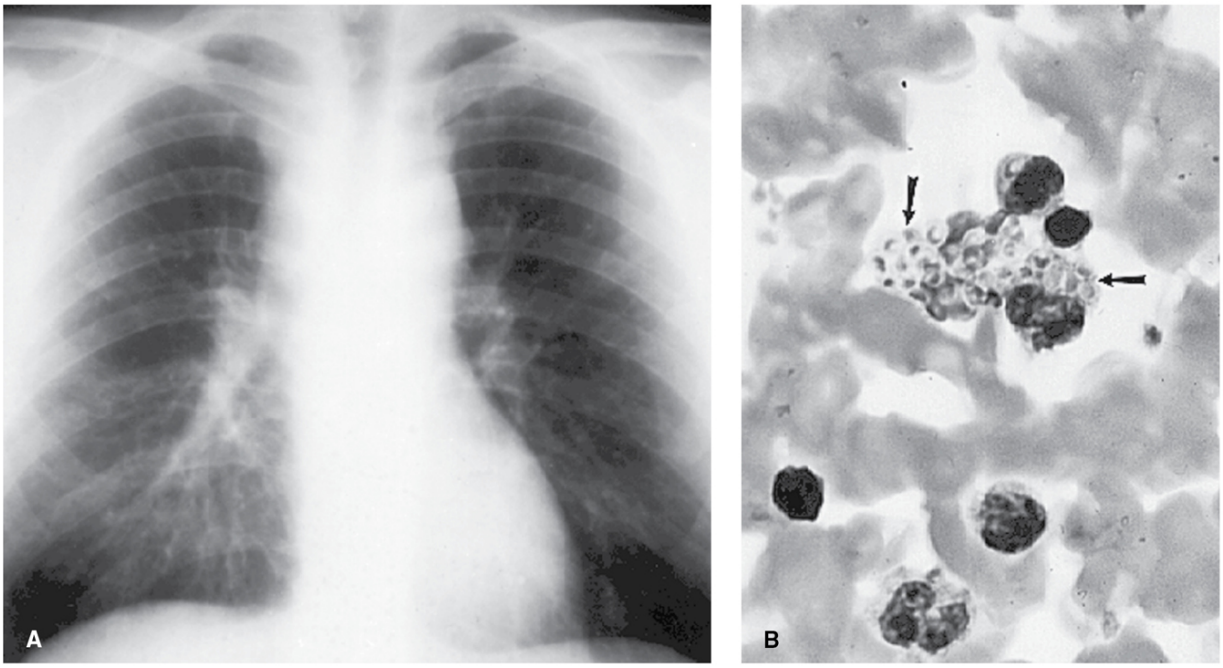

Figure 78-4 Histoplasmosis infection. A, Chest radiograph showing bilateral interstitial infiltrate. B, Gram stain of peripheral blood showing leukocytes with intracellular organisms.

The treatment benefits of antifungal therapy in systemic histoplasmosis have not been well investigated. Treatment options for histoplasmosis are outlined in **Table 78-7**.[138] Accordingly, J.N. should be treated with an IV amphotericin product or itraconazole 2.8 mg/kg/day, and his course of therapy should be monitored for both efficacy and toxicity. The decision was made to use conventional amphotericin for J.N.

Table 78-7
Treatment of Histoplasmosis

Disease	Primary	Secondary
Acute Pulmonary		
Prolonged symptomatology (>2 weeks)	Resolves spontaneously	N/A
Immunocompromised[a]	ITZ 50–100 mg/day (3–6 months)[b]	AmB 0.3–0.5 mg/kg/day[b]

Respiratory distress	AmB lipid formulation 3–5 mg/kg/day[a]	AmB 0.3–0.5 mg/kg/day
(Pa_{O_2} >70 mm Hg)	AmB 0.5–1.0 mg/kg/day	ITZ 1.5–2.8 mg/kg/day (≥6 months)[b]
	(TD 250–500 mg) ± corticosteroids (methylprednisolone 0.5–1 mg/kg) × 1–2 weeks	ITZ (has not been investigated in life-threatening situations)
Chronic Pulmonary		
Active	ITZ (1.5–2.8 mg/kg/day 9 months)[b,c]	AmB 0.5 mg/kg/day[c]
Inactive		or KTZ 400 mg/day (≈6 months)
Histoplasmoma	No treatment	N/A
Mediastinal fibrosis	Surgery[d]	N/A
Systemic Disease		
	AmB (TD recommended: 35 mg/kg) or lipid AmB then ITZ 2.8 mg/kg/day × up to 12 months[b]	Fluconazole 400–800 mg/day[e]

AmB, amphotericin B-deoxycholate; ITZ, itraconazole; KTZ, ketoconazole; TD, total dose.

[a]Lipid formulations of amphotericin B are preferable to generic amphotericin B in patients infected with HIV.[148]

[b]Treatment should be continued until the patient is symptom-free and culture-negative for 3 months. The recommendations for duration of therapy or total doses should be used only as guides for initial therapy based on the IDSA 2007 guideline.[147]

[c]Indicated only for serious symptoms (ie, hemoptysis).

[d]ITZ 200 mg daily or twice a day for 6–18 months for most patients.

[e]Fluconazole should only be used in patients who cannot take ITZ.

Blood and urine cultures, WBC and platelet counts (histoplasma is associated with pancytopenia), constitutional symptoms, serum lactate dehydrogenase, and hepatosplenomegaly are useful

measures for evaluating the outcome of antifungal therapy of J.N.'s histoplasmosis. Anemia and chest radiographs are poor measures of treatment response. Chest radiographs often reflect calcified granulomas in chronic disease with scarring, which rarely resolve even with extensive therapy. Therefore, evaluation of deterioration on radiograph, but not of improvement, is possible. In addition, AmB-induced renal disease with secondary anemia can confuse evaluation of disease resolution. Anemia must be excluded as a prognostic indicator in patients receiving AmB for durations of 3 weeks regardless of the dose.[100]

Diligent follow-up of patients is required because relapses occur in 5% to 15% of AmB-treated patients within 3 years. Relapses have occurred in patients who received <30 mg/kg total dose of generic AmB or had concomitant untreated Addison disease, immunosuppression, vascular infections (endocarditis, grafts, and aneurysms), or meningeal infections.[138] More than 90% of HIV-positive patients experience a relapse of histoplasmosis subsequent to adequate AmB therapy. A double-blind trial in immunocompromised patients (HIV) revealed that liposomal AmB was superior to AmB deoxycholate. It is not known how itraconazole is compared with liposomal AmB in those coinfected with HIV. If this patient was coinfected with HIV, a lipid-based amphotericin is preferred.[139] Even the initiation of subsequent immunosuppressive therapy is of particular concern because of the potential for reactivation (relapse) and dissemination of histoplasmosis from dormant foci, especially in patients with residual granulomas. The residual disease has been hypothesized to lead to chronic inflammatory responses and secondary strokes.[140]

Potential adverse effects to AmB should also be monitored in J.N. (eg, infusion-related reactions, nephrotoxicity, anemia, hypokalemia, neurotoxicity, and thrombophlebitis). In addition, J.N.'s adrenal status should be monitored closely because of his long-term corticosteroid therapy and his histoplasmosis. Patients who are addisonian secondary to histoplasmosis infections appear to experience more episodes of AmB-induced acute hypotension.

AZOLE ADVERSE EFFECTS

CASE 78-6, QUESTION 2: After treatment with a total AmB dose of 750 mg, clinical improvement in J.N.'s histoplasmosis is subjectively and objectively documented. The clinician selected ketoconazole 400 mg/day as an oral substitute for his AmB regimen because of the patient's economic circumstances. Six weeks later, J.N. reports impotence and wonders whether this could be caused by his medication. What is the likelihood that ketoconazole is the cause of J.N.'s impotence?

Ketoconazole has been associated with more adverse reactions and greater potential for drug interactions compared with itraconazole and fluconazole. The most common side effects of ketoconazole, however, are nausea and vomiting. GI distress is dose-related, with fewer GI effects with 400 mg/day compared with 800 mg/day.[138] Endocrine and hepatic toxicities are the most significant adverse effects of ketoconazole. Dose-splitting from daily to twice daily may decrease nausea and vomiting. Dose-related endocrinologic toxicities (hypoadrenalism, oligospermia, and diminished libido) have been observed during ketoconazole therapy secondary to the inhibition of mammalian sterol synthesis[13,141] and usually have been resolved with drug discontinuation. Therefore, J.N.'s impotence might well be attributed to his ketoconazole. Liver enzymes should also be monitored because an approximate 10% risk exists of elevation in transaminases and an occasional case of serious hepatitis and hepatic failure.[13,141]

The triazoles—itraconazole, fluconazole, and voriconazole—are much better tolerated and require less monitoring than ketoconazole therapy. This result has been attributed to the greater affinity of the triazoles for fungal cytochrome enzymes and less interference with mammalian enzymes.[142] Itraconazole, fluconazole (6 mg/kg/day), and voriconazole do not exhibit antiandrogenic effects, and nausea and vomiting are less common when compared with imidazoles. Abnormal elevations in liver function have been reported in 2.7% of patients receiving voriconazole during clinical trials. Abnormalities in liver function tests may be associated with higher azole dosages or

serum concentrations but generally resolve either with continued therapy or dosage modification, including drug discontinuance. Liver function should be determined before and periodically throughout azole therapy because cases of serious hepatic reactions have been reported.[142] A unique adverse event associated with voriconazole is enhanced perception to light, which may be associated with higher plasma concentrations or doses. Generally, drug discontinuance is not required, although monitoring of visual acuity, visual field, and color perception is advised if therapy lasts longer than 28 days. Diarrhea, asthenia, flatulence, and eye pain have been reported with posaconazole therapy.[53] Based on these data, J.N. should be given a trial of itraconazole.

AZOLE–DRUG INTERACTIONS

Case 78-6, Question 3: J.N. chose to continue his ketoconazole therapy. He now returns with Cushingoid signs and symptoms. What potential drug or disease state interaction could be implicated as a cause of this serious problem in J.N.?

Drug interactions with systemic azoles and polyenes vary from mild inconveniences to life-threatening events. Historically, the interaction between azoles and nonsedating H_1-selective antihistamines has been serious, leading to QT prolongation and ventricular arrhythmias.[143] Although it is possible that concomitant use of corticosteroids could reduce antifungal efficacy, no clinical trial has addressed this important question. Corticosteroid serum concentrations can double with concomitant use of ketoconazole, leading to recommendations to decrease the steroid dose by 50% when ketoconazole is used. The interaction has been suggested between glucocorticoids and other azoles.[144] In addition, dexamethasone has been demonstrated to increase the clearance of caspofungin.

Other significant drug interactions with the azole antifungals involve their ability to inhibit the CYP450 enzyme system. All azoles

inhibit CYP3A4, but with varying potency: Ketoconazole is the most potent inhibitor, followed by itraconazole and voriconazole, then posaconazole and fluconazole. Data on relative inhibition potency for isavuconazole are still pending. In addition to therapeutic interactions, numerous other agents are substrates to cytochrome CYP3A4 but have yet to be evaluated. Because azole antifungals could increase serum concentrations with associated potential toxicity, caution should be exercised during concomitant use. Adding complexity to voriconazole's interactions includes its propensity to inhibit CYP2C9 and CYP2C19, two isoenzymes exhibiting polymorphism, thus increasing concentrations of CYP2C9 or CYP2C19 substrates. Conversely, agents that either induce or inhibit the CYP450 system may decrease or increase, respectively, antifungal drug concentrations. Posaconazole is a substrate for *p*-glycoprotein efflux and is metabolized via uridine diphosphate glucuronidation; therefore, inhibitors or inducers of these clearance pathways may affect posaconazole concentrations.[51–53]

Although hundreds of drug interactions have been documented with antifungals (particularly azoles), the number of theoretical interactions probably exceeds 2000.[145] Therefore, patient medication profiles should be carefully screened before initiating and stopping antifungal therapy to assess the risk for serious drug interactions. Preferably, this screening should be performed with a frequently updated computerized interaction database, which are available commercially (Lexicomp) or free of cost (www.fungalpharmacology.org), including software for use on smartphones.

Coccidioidomycosis

SEROLOGIC TESTS

CASE 78-7

Question 1: F.W., a 32-year-old Filipina female and a lifelong resident of the Central Valley in California, is admitted to the hospital with a third recurrence of

coccidioidal meningitis. Approximately 4 years ago, she was treated with a total AmB dose of 2.2 g, which resulted in a good clinical response. Nine months later, she relapsed and received a second course of AmB to a total of 1.6 g. She did well during the next 18 months and was able to return to work as a secretary. Over the past 4 months, however, F.W. has had chronic headaches, has been unable to concentrate at work, and is reported by family members to have a very labile personality. A computed tomography (CT) scan of the brain reveals mild hydrocephalus. An opening pressure of 19 mm Hg (normal, 10 mm Hg) was documented at lumbar puncture. Analysis of the CSF showed:

110 WBC/μL (normal, 0 WBC/μL)
Glucose, 18 mg/dL (normal, 60% of serum glucose)
Protein, 190 mg/dL (normal, >50 mg/dL)
CF antibodies were positive in the CSF at a titer of 1:32.

How should serologic tests for coccidioidomycosis be interpreted?

The most important serologic tests for fungal infections use CF, immunodiffusion, and EIA techniques. Tests for complement-fixing antibodies (ie, CF) to the dimorphic fungi (see **Table 78-1**) are well established, and various antigens have been used. Coccidioidin is the mycelial-phase antigen for *Coccidioides immitis*. Of patients with coccidioidomycosis, 61% will have coccidioidin CF titers of at least 1:32, and 41% will have titers of 1:64. Rising titers are a bad prognostic sign, and falling titers indicate clinical improvement. Therefore, F.W.'s CSF CF titer of 1:32 is consistent with active coccidioidomycosis. Immunodiffusion testing for coccidioidomycosis using coccidioidin reveals that seropositive results appear 1 to 3 weeks after the onset of primary infection in 75% of patients, and this positivity usually disappears within 4 months if the infection resolves.[146] IgG-specific and IgM-specific EIAs using a combination of antigens for *C. immitis* have been developed. These tests offer sensitivities of more than 92% and specificities of 98% for serum and CSF. EIA reactivity appears earlier than CF reactivity.[147,148]

ANTIFUNGAL CENTRAL NERVOUS SYSTEM PENETRATION

CASE 78-7, QUESTION 2: What is a pharmacokinetic explanation for the treatment failure of F.W.? How might this problem be overcome?

F.W. has received prolonged parenteral AmB administration, and the CSF still contains fungal organisms. Treatment failures in this case may partly be owing to the limited penetration of free AmB into the CSF.[88] Because generic AmB or lipid formulation–dissociated AmB is highly bound to lipid (90%–95%), CSF concentrations achieved are only 2% to 4% of the serum concentration[88],[142]; peritoneal, synovial, and pleural fluid concentrations are <50% of the serum concentrations (see **Table 78-5**). Flucytosine is not significantly bound to protein and penetrates the CSF, vitreous, and peritoneal fluids; its volume of distribution approximates that of total body water.[149] Flucytosine concentration in the CSF is 74% of the serum concentration, resulting in its extensive use in the treatment of CNS mycoses, particularly cryptococcal meningitis. Flucytosine, however, has no activity in coccidioidomycosis and, therefore, cannot be used in F.W.

The volume of distribution of fluconazole approaches that of total body water,[150] and concentrations of fluconazole in CSF are ~60% of simultaneous serum concentrations. Ketoconazole penetrates CSF poorly because it is highly bound to plasma proteins (>80%) and to erythrocytes (15%). Itraconazole is similar to ketoconazole in that it is >99% protein bound. Itraconazole concentrates intracellularly in host alveolar macrophages, which may account for its efficacy against some fungal CNS infections despite its inability to penetrate into the CSF.[151] Echinocandins also poorly (>5%) penetrate into the CSF. Reliable data on terbinafine, isavuconazole, and posaconazole penetration are currently unavailable. Therefore, fluconazole might be an alternative to CNS instillation of AmB based on pharmacokinetic considerations.[152],[153]

Fluconazole, investigated at dosages of 400 mg/day, is useful in patients with coccidioidomycosis meningitis. Similar to amphotericin products, relapse rates are high once fluconazole therapy is stopped. Oral itraconazole 200 mg twice daily was not found to be superior to fluconazole in a controlled trial of nonmeningitis disease; however, a trend toward greater efficacy was observed, particularly in skeletal disease.[154]

INTRATHECAL AMPHOTERICIN

CASE 78-7, QUESTION 3: What adverse events might be observed with the intrathecal administration of an antifungal in F.W.?

Augmentation of systemic antifungal administration with intraventricular or intrathecal administration may improve the outcome for antifungals with poor penetration into the CSF. Intrathecal generic AmB doses in adults normally range from 0.25 to 0.5 mg diluted in 5 mL of 5% glucose.[155],[156] A few studies suggest that doses larger than 0.7 mg improve the cure rate and decrease relapse. Cisternal or intraventricular administration is recommended as the routes of choice because of flow characteristics of CSF from the ventricles to the spinal cord. When lumbar administration has been necessary, agents are administered in a hypertonic solution of 10% glucose, and the patient is placed in a Trendelenburg position in an attempt to improve distribution of the drug to the basilar meninges and ventricles and reduce local toxicity. Voriconazole, caspofungin, and the lipid amphotericin formulations have been used, but not evaluated in controlled trials.

Cisternal antifungal administration has been associated with headaches, nausea, vomiting, cranial nerve paresis, and cisternal hemorrhage caused by needle trauma. An Ommaya reservoir often is used to facilitate intraventricular administration of AmB formulations. Common complications of these devices include shunt occlusion, bacterial colonization or bacterial meningitis, Parkinsonian symptoms, and seizures.[156–158] In the past, lumbar administration was used because it is simpler, but it often must be discontinued because of chemical arachnoiditis, headache, transient radiculitis, paresthesia, nerve pulses, difficulty voiding, impaired vision, vertigo, and tinnitus. Acute toxic delirium, demyelinating peripheral neuropathy, and spinal cord injury have also been reported.[159–162] Regardless of the substantial and serious adverse effects, intraventricular administration may be effective in treating patients

with meningitis who have severe disease or who are pharmacologic nonresponders.

Aspergillosis

EMPIRIC THERAPY (NEUTROPENIC HOST)

CASE 78-8

QUESTION 1: M.Z., an otherwise healthy 29-year-old male, received an allogeneic stem cell transplantation 12 days ago. He has had no serious complications associated with his chloroquine-induced aplastic anemia during his 7-month wait for transplant. On transplant Days 5 to 2, induction therapy was initiated with cyclophosphamide (50 mg/kg) and total body irradiation, and then bone marrow from his human leukocyte antigen–compatible brother was infused on day 0. The onset of neutropenia was noted on day 3, and the WBC count was 50 cells/μL. M.Z. has reported only of stomatitis and diarrhea before day 5. On that morning, he was reporting fever, chest pain, and headache. On physical examination, his temperature was 98.6 °F (37 °C). Empiric antibiotics were added, but by day 8, he was not clinically improving. A CT scan of the chest and sinuses revealed a nodular pleural–based opacity with ground-glass attenuation (halo sign) in his right lung.

What therapeutic options should be considered for this patient?

Empiric antifungal therapy in a neutropenic host should be initiated when a patient is febrile for more than 96 hours on appropriate antibiotics. Routine empiric therapy for a patient without evidence of deep-seated fungal infection was historically generic AmB 0.3 to 0.6 mg/kg/day or fluconazole 200 to 400 mg/day until the absolute neutrophil count is >500 cells/μL.[163] Therapy results in the resolution of signs and symptoms in up to 64% of patients.

CASE 78-8, QUESTION 2: What is the role of lipid formulations of AmB?

Because mold infections are of concern in this neutropenic patient who received an allogeneic stem cell transplant, mold-active antifungal therapy should be started immediately. In a large, well-controlled, double-blind study, AmB 0.6 mg/kg/day was compared

with liposomal AmB 3.0 mg/kg/day in febrile neutropenic patients. Patients who were febrile for more than 96 hours and neutropenic (>500 cells/μL) experienced equal survival and clinical success of ~50% for both the agents.[164] Success rates have been similar with other agents, including liposomal AmB (34%), caspofungin (34%),[165] voriconazole, or itraconazole.[166],[167] It is important to remember that fever is a late and insensitive measure of infection. Prevention of breakthrough invasive fungal infection may be the most important indicator of an agent's efficacy. Using this measure comparing the various trials, voriconazole appears to be the most effective agent (voriconazole vs liposomal AmB [1.9% vs 5%] and AmB versus liposomal AmB [3.2% vs 7.8%]), although crude mortality rates were similar in the two patient groups (8% vs 6%, respectively).[164],[167] Selection of expensive, but less toxic, agents should be weighed against the morbidity and mortality associated with invasive fungal disease.

TREATMENT OF ASPERGILLOSIS

CASE 78-8, QUESTION 3: Fiber optic bronchoscopy performed to evaluate the nodular lesion in chest CT revealed eroded bronchioles with necrotic tissue, and methenamine silver nitrate stain of a biopsy sample revealed fragmented, closely septated hyphal bodies branched at 45° angles. The samples were sent to microbiology for cultures. A galactomannan test from the bronchial wash was positive at an index of 1.1. All previous blood and sputum cultures have been negative. The diagnosis at this time is probable aspergillosis. What treatment steps should be taken?

Drug therapy should be approached by first determining whether the infection is likely to be invasive or noninvasive disease (**Fig. 78-5**). Most patients inhale *Aspergillus* species and never become symptomatic or exhibit only mild hypersensitivity pneumonitis. Pepper can be a common food source for *Aspergillus* exposure. Invasive infections are more likely to occur in immunocompromised patients, especially those with prolonged neutropenia or patients who receive high dose (ie, more than 1 mg/kg/day prednisone

equivalent) or corticosteroids or other T-cell immunosuppressive therapy (ie, alemtuzumab and anti-thymocyte globulin) to treat acute graft-versus-host disease following stem cell transplantation or organ rejection after solid organ transplantation. Allogeneic hematopoietic stem cell transplantation (HSCT) has a much greater infection rate and mortality compared with autologous HSCT.[168] A classic observation reported by radiology is a “halo” sign or a “crescent” sign identified on CT, which is highly suggestive of invasive aspergillosis. However, the halo sign is not specific, because other bacterial viral, malignant, or autoimmune conditions can produce similar radiographic findings. The halo sign is also transient and is less common after 1 week of infection. Typically, these nodular lesions will enlarge (even with effective antifungal therapy) and then cavitate when a patient’s neutrophil count recovers, forming another distinguishing CT abnormality for invasive mold disease—the air crescent sign.[169]

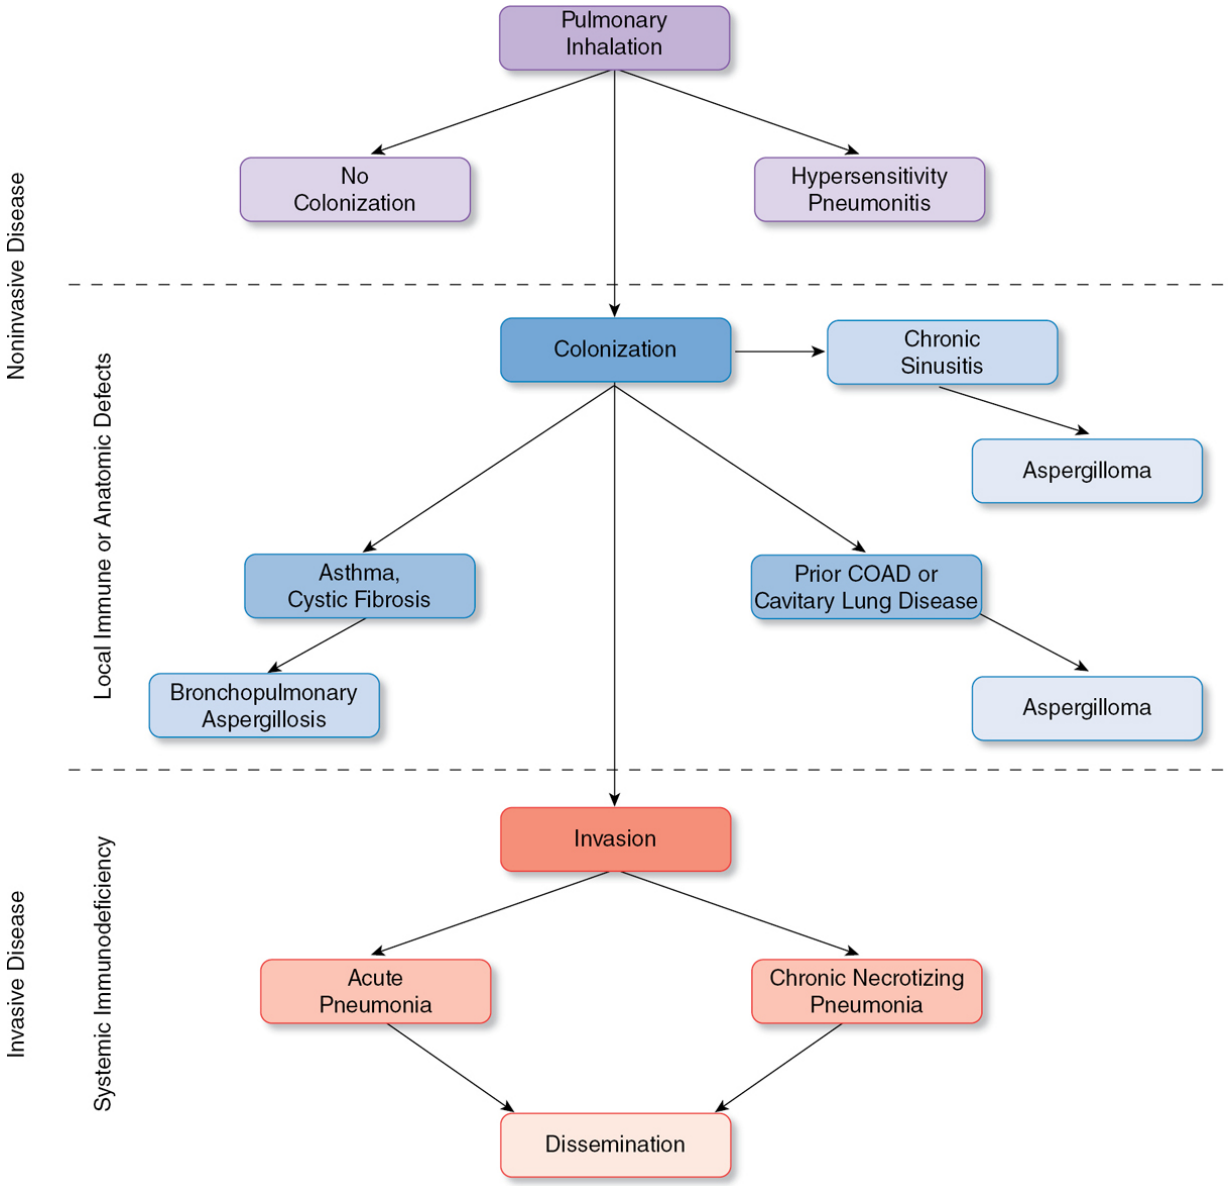

Figure 78-5 Classification of aspergillosis infections. COAD, chronic obstructive airway disease.

A majority invasive aspergillosis cases are now diagnosed based on a compatible clinical and radiographic picture described above and the results of an ELISA antigen test for a cell wall polysaccharide in *Aspergillus* spp.-galactomannan. Serum galactomannan test is a fairly sensitive and specific test (80%–90%) in neutropenic patients with aspergillosis who rapidly progress to angioinvasive disease in the lung. The test is less sensitive in non-neutropenic patients who initially present with bronchial invasive

patterns of pneumonia before angioinvasion or in patients receiving mold-active antifungal therapy.[170] In these populations, testing of bronchial alveolar lavage fluid for galactomannan antigen has better sensitivity than serum. False-positive test findings have been associated with *Bifidobacterium* spp. colonization in pediatric GI tracts, other eukaryotic infections (ie, *Trichosporon*, *Fusarium*, *Saccharomyces*, *Histoplasma*, or *Acremonium*), and administration of piperacillin–tazobactam or calcium gluconate, which is of concern for clinicians using this test for screening in areas with low case rates. Galactomannan antigen is a useful prognostic indicator for therapeutic outcome in confirmed cases or as a screen in areas with high case rates. The subjective and objective data in this case clearly represent invasive symptomatic disease necessitating aggressive treatment.
